The decay $Z_c(3900)^\pm \rightarrow \omega \pi^\pm$ is searched for using data samples collected with the BESIII detector operating at the BEPCII storage ring at center-of-mass energies $\sqrt{s} = 4.23$ and 4.26 GeV. No significant signal for the $Z_c(3900)^\pm$ is found, and upper limits at the 90% confidence level on the Born cross section for the process $e^+e^- \rightarrow Z_c(3900)^\pm \rightarrow \omega \pi^+\pi^-$ are determined to be 0.26 and 0.18 pb at $\sqrt{s} = 4.23$ and 4.26 GeV, respectively.
I. INTRODUCTION

Recently, in the study of the process $e^+e^-\rightarrow J/\psi\pi^+\pi^-$, a distinct charged structure, named the $Z_c(3900)^\pm$, was observed in the $J/\psi\pi^\pm$ spectrum by BESIII [1] and Belle [2]. Its existence was confirmed shortly thereafter with CLEO-c data [3]. The existence of the neutral partner in the decay $Z_c(3900)^0 \rightarrow J/\psi\pi^0$ has also been reported in CLEO-c data [3] and by BESIII [4]. The $Z_c(3900)$ is a good candidate for an exotic state beyond simple quark models, since it contains a $c\bar{c}$ pair and is also electrically charged. Noting that the $Z_c(3900)$ has a mass very close to the $D^*\bar{D}$ threshold (3875 MeV), BESIII analyzed the process $e^+e^-\rightarrow \pi^\pm(D\bar{D}^*)^\mp$, and a clear structure in the $(D\bar{D}^*)^\mp$ mass spectrum is seen, called the $Z_c(3885)$. The measured mass and width are $(3883.9\pm1.5\pm4.2)$ MeV/$c^2$ and $(24.8\pm3.3\pm11.0)$ MeV, respectively, and quantum numbers $J^P = 1^+$ are favored [3]. Assuming the $Z_c(3885) \rightarrow D\bar{D}^*$ and the $Z_c(3900) \rightarrow J/\psi\pi$ signals are from the same source, the ratio of partial widths $\Gamma(Z_c(3900)^0 \rightarrow D\bar{D}^*)/\Gamma(Z_c(3900)^0 \rightarrow J/\psi\pi)$ is determined to be $6.2\pm1.1\pm2.7$.

The observation of the $Z_c(3900)$ has stimulated many theoretical studies of its nature. Possible interpretations are tetra-quark [3], hadro-charmonium [7], $D^*\bar{D}$ molecule [4] and threshold effects [3,11]. Lattice QCD studies provide theoretical support for the existence of $X(3872)$ [12] but not for the $Z_c(3900)$ [13,14]. However, those studies were carried out on small volumes with unphysically heavy up and down quarks. It is also worth noting that no resonant structure in $J/\psi\pi$ is observed in $B\rightarrow J/\psi\pi\pi^\pm$ by LHCb [15], in $B^0 \rightarrow J/\psi K^-\pi^+$ by Belle [16] or in $\gamma\nu \rightarrow J/\psi\pi^+\pi^-$ by COMPASS [17].

The decay properties of a state can provide useful information on its internal structure. There are three important decay modes for charmonium-like states: (i) “fall-apart” decays to open charm mesons; (ii) cascades to hidden charm mesons; and (iii) decays to light hadrons via intermediate gluons. In addition, as shown in Ref. [3,10], an enhancement near the $DD^*$ threshold can be produced via rescattering of hidden or open charm final states. Decays of the $Z_c(3900)$ to light hadrons can play a unique role in distinguishing a resonance from threshold effects, because the decay mode with $c\bar{c}$ annihilation involves neither hidden nor open charm final states. However, theoretical estimates of annihilation widths to light hadrons are only order of magnitude due to uncertainties of wave function effects and QCD corrections [21,22]. A sizeable $Z_c(3900)$ decay width to light hadrons might be expected in analogy to $\eta_c$ or $\chi_{cJ}$ into hadronic final states.

Among a large number of hadronic final states that are available for a $J^I(J^P) = 1^-(1^+)$ resonance decay, $\omega\pi$ is one of the typical decay modes which are not suppressed by any known selection rule. In this paper, we report a search for $Z_c(3900)^\pm \rightarrow \omega\pi^\pm$ based on $e^+e^-$ annihilation samples taken at center-of-mass (CM) energies $\sqrt{s} = 4.23$ and 4.26 GeV. The data samples were collected with the BESIII [23] detector operating at the BEPCII storage ring. The integrated luminosity of these data samples are measured by analyzing the large-angle Bhabha scattering events with an uncertainty of 1.0% [24] and are equal to 1092 pb$^{-1}$ and 826 pb$^{-1}$, for $\sqrt{s} = 4.23$ and 4.26 GeV, respectively.

II. BESIII EXPERIMENT AND MONTE CARLO SIMULATION

The BESIII detector, described in detail in Ref. [23], has a geometrical acceptance of 93% of $4\pi$. A small-cell helium-based main drift chamber (MDC) provides a charged particle momentum resolution of 0.5% at 1 GeV/$c$ in a 1 T magnetic field, and supplies energy-loss ($dE/dx$) measurements with a resolution of 6% for minimum-ionizing pions. The electromagnetic calorimeter (EMC) measures photon energies with a resolution of 2.5% (5%) at 1 GeV in the barrel (end-caps). Particle identification (PID) is provided by a time-of-flight system (TOF) with a time resolution of 80 ps (110 ps) for the barrel (end-caps). The muon system, located in the iron flux return yoke of the magnet, provides 2 cm position resolution and detects muon tracks with momenta greater than 0.5 GeV/$c$.

The GEANT4-based [25] Monte Carlo (MC) simulation software BOOST [26] includes the geometric description of the BESIII detector and a simulation of the detector response. It is used to optimize event selection criteria, estimate backgrounds and evaluate the detection efficiency. We generate signal MC samples of $e^+e^-\rightarrow Z_c(3900)^\pm\pi^\pm \rightarrow \omega\pi^+\pi^-\pi^0$ uniformly in phase space, where the $\omega$ decays to $\pi^+\pi^-\pi^0$. The decays of $\omega \rightarrow \pi^+\pi^-\pi^0$ are generated with the $OMEGA_{\text{DALITZ}}$ model in EVGEN [27,28]. Initial state radiation (ISR) is simulated with KKMC [29,30], where the Born cross section of $e^+e^-\rightarrow Z_c(3900)^\pm\pi^\pm$ is assumed to follow a $Y(4260)$ Breit-Wigner (BW) line shape with resonance parameters taken from the Particle Data Group (PDG) [31]. Final state radiation (FSR) effects associated with charged particles are handled with PHOTOS [29]. For studies of possible backgrounds, inclusive $Y(4260)$ MC samples with luminosity equivalent to the experimental data at $\sqrt{s} = 4.23$ and $\sqrt{s} = 4.26$ GeV are generated, where the main known decay channels are generated using EVGEN [27,28] with branching fractions taken from the PDG [31]. The remaining events associated with charmonium decays are generated with LUNDCHARM [32], while continuum hadronic events are generated with PYTHIA [33]. QED processes such as Bhabha scattering, dimuon and digamma events are generated with KKMC [24,30].
III. DATA ANALYSIS AND BACKGROUND STUDY

Tracks of charged particles in BESIII are reconstructed from MDC hits. We select tracks with their point of closest approach within ±10 cm of the interaction point in the beam direction and within 1 cm in the plane perpendicular to the beam. Information from the TOF and dE/dx measurements are combined to form PID confidence levels for the π and K hypotheses; each track is assigned to the particle type with the highest confidence level.

Photon candidates are reconstructed by clustering EMC crystal energies. The efficiency and energy resolution are improved by including energy deposits in nearby TOF counters. The minimum energy is required to be 25 MeV for barrel showers (|cosθ| < 0.80) and 50 MeV for endcap showers (0.86 < |cosθ| < 0.92). To exclude showers from charged particles, the angle between the shower and the extrapolated charged tracks at the EMC must be greater than 5°. A requirement on the EMC cluster timing with respect to the event start time is applied to suppress electronic noise and energy deposits unrelated to the event.

The π^0 candidates are formed from pairs of photons that can be kinematically fitted to the known π^0 mass. The χ^2 from this fit with one degree of freedom is required to be less than 25.

Events with exactly four charged tracks identified as pions with zero net charge and at least one π^0 candidate are selected. A five-constraint kinematic fit (5C) is performed to the hypothesis of e^+e^- → π^+π^-π^+π^-π^0 (constraints are the 4-momentum of the initial e^+e^- system and the π^0 mass), and χ^2_{5C} < 40 is required. If there more than one π^0 is found in an event, the combination with the smallest χ^2_{5C} is retained.

Figure 1 shows the π^+π^-π^0 invariant mass distribution of the π^+π^-π^0 combination with invariant mass closest to the mass of ω for the selected candidate e^+e^- → π^+π^-π^+π^-π^0 events at √s = 4.23 GeV, where prominent η, ω and φ signals are observed.

ω candidates are selected with the mass window |M(π^+π^-π^0)_{closest} − m_ω| < 0.03 GeV/c^2, where m_ω is the nominal mass of the ω taken from the PDG [31]. Figure 2 shows the M(ωπ^±) distribution for the candidate events of e^+e^- → ωπ^±π^- at √s = 4.23 GeV. No sign of a peak near 3.9 GeV/c^2 is apparent. The shaded histogram in Fig. 2 shows the distribution of non-ω background for the events in ω sideband regions (0.06 < |M(π^+π^-π^0)_{closest} − m_ω| < 0.09 GeV/c^2).

By studying inclusive MC samples with luminosity equivalent to the data at √s = 4.23 and 4.26 GeV, the background is found to be dominantly from the continuum process e^+e^- → ωπ^+π^- - . The solid histogram in Fig. 2 shows the ωπ^± invariant mass distribution for events selected from the inclusive MC sample.

IV. FITTING RESULTS

We use a one-dimensional, unbinned, extended maximum likelihood fit to the ωπ^± invariant mass distribution to obtain the yield of Z_c(3900)^± → ωπ^± events. The signal probability density function (PDF) is parameterized by an S-wave Breit-Wigner function convolved with a Gaussian resolution function and weighted with the detection efficiency:

\[ G(M; \sigma) \propto \frac{e^{M}}{(M^2 - M_0^2)^2 + M_0^2\Gamma^2} \times \varepsilon(M) , \]

where G(M; σ) is a Gaussian function representing the mass resolution. The mass resolution of the Z_c(3900)^± is 1.2 ± 0.1 MeV/c^2 at both √s = 4.23 and 4.26 GeV,
according to MC simulation. \( p \cdot q \) is the S-wave phase space factor, where \( p \) is the \( Z_c(3900)^\pm \) momentum in the \( e^+e^- \) CM frame and \( q \) is the \( \omega \) momentum in the \( Z_c(3900)^\pm \) CM frame. \( M \) is the invariant mass of \( \omega\pi^\pm \), and \( M_0 \) and \( \Gamma \) are the mass and width of the \( Z_c(3900)^\pm \), which are fixed to the results in Ref. [1]. \( \epsilon(M) \) is the efficiency curve as a function of the \( \omega\pi^\pm \) invariant mass, obtained from signal MC simulation.

The background shape is described by an ARGUS function \( M \sqrt{1 - (M/m_0)^2} \cdot \exp(\epsilon(1 - (M/m_0)^2)) \), where \( \epsilon \) is left free in the fit and \( m_0 \) is fixed to the threshold of \( \sqrt{s} - m_\pi \). [4]

Figure 3(a) shows the fit result for the data sample at \( \sqrt{s} = 4.23 \) GeV. The fit yields 14 ± 11 events for the \( Z_c(3900)^\pm \) signal. Compared to the fit without the \( Z_c(3900)^\pm \) signal, the change in \( \ln L \) with \( \Delta(d.o.f.) = 1 \) is 0.74, corresponding to a statistical significance of 1.2σ. Using the Bayesian method [31, Sect.38.4.1], the upper limit for the \( Z_c(3900)^\pm \) signal is set to 33.5 events at the 90% confidence level (C.L.), where only the statistical uncertainty is considered.

The fit result for the data sample at \( \sqrt{s} = 4.26 \) GeV is shown in Fig. 3(b). The fit yields 2.2 ± 8.1 events for the \( Z_c(3900)^\pm \) with a statistical significance of 0.1σ. The upper limit is 18.8 events at the 90% C.L.

V. CROSS SECTION UPPER LIMITS AND SYSTEMATIC UNCERTAINTY

The upper limit on the Born cross section at the 90% C.L. is calculated as

\[
\sigma(e^+e^- \rightarrow Z_c(3900)^\pm \pi^\pm, Z_c(3900)^\pm \rightarrow \omega\pi^\pm) = \frac{N^{UL}}{L_{int}(1 + \delta) \cdot |1 - \Gamma| \cdot |1 - \sigma_e| B_\omega B_\pi e^\sigma},
\]

where \( N^{UL} \) is the upper limit on the signal events; \( L_{int} \) is the integrated luminosity; \( \epsilon \) is the selection efficiency obtained from signal MC simulation, which are 18.5±0.2% and 18.6±0.2% at \( \sqrt{s} = 4.23 \) and 4.26 GeV, respectively; \( \sigma_e \) is the systematic uncertainty of the efficiency described in next paragraph; \( \frac{1}{1 - \Gamma} \) is the vacuum polarization factor obtained by using calculations from Ref. [32], and equal to 1.06 for both energies; \( 1 + \delta \) is the radiative correction factor, equal to 0.844 for \( \sqrt{s} = 4.23 \) GeV and 0.848 for \( \sqrt{s} = 4.26 \) GeV obtained using Ref. [24, 30] by assuming the line shape of Born cross section \( \sigma(e^+e^- \rightarrow Z_c(3900)^\pm \pi^\pm) \) to be a BW function with the parameters of the \( Y(4260) \) taken from PDG [31]; and \( B_\omega \) and \( B_\pi \) are the branching fractions of the decay \( \omega \rightarrow \pi^+\pi^-\pi^0 \) and \( \pi^0 \rightarrow \gamma\gamma \) [31], respectively. A conservative estimate of the upper limit of the Born cross section is determined by lowering the efficiency by one standard deviation of the systematic uncertainty.

The systematic uncertainty of the cross section measurement from Eq. 2 is summarized in Table III. The luminosity is measured using Bhabha events with an uncertainty of 1.0%. [24]. The uncertainty in tracking efficiency for pions is 1.0% per track [3], i.e. 4.0% for the track selection in this analysis. The uncertainty in PID efficiency for pions is 1.0% per track [5]. The uncertainty in the photon reconstruction efficiency is less than 1% per photon [36]. The uncertainty in the \( \pi^0 \) reconstruction efficiency is 2.0%. [37]. The uncertainty of the kinematic fit is estimated by correcting the helix parameters of the charged tracks. The detailed procedure to extract the correction factors can be found in Ref. [38]. The track parameters in MC samples are corrected by these factors, and the difference in efficiencies of 0.8% with and without the correction is taken as the systematic uncertainty associated with the kinematic fit. An MC sample generated with \( Z_c(3900)^\pm \rightarrow \omega\pi^\pm \) in both S wave and D wave, assuming a \( D/S \) waves amplitude ratio of 0.1, results in a 3% change in detection efficiency. This difference is taken as the systematic uncertainty associated with the MC production model. The branching ratio value for \( \omega \rightarrow \pi^+\pi^-\pi^0 \) comes from the PDG [31], and its error is
TABLE I. Summary of the relative systematic uncertainties of the cross section measurement (in %).

| Source                  | $\sqrt{s} = 4.23$ GeV | $\sqrt{s} = 4.26$ GeV |
|-------------------------|------------------------|------------------------|
| Luminosity              | 1.0                    | 1.0                    |
| Tracking                | 4.0                    | 4.0                    |
| PID                     | 4.0                    | 4.0                    |
| Photon reconstruction   | 2.0                    | 2.0                    |
| $\pi^0$ reconstruction  | 2.0                    | 2.0                    |
| Kinematic fit           | 0.8                    | 0.8                    |
| Decay model             | 3                      | 3                      |
| Radiative correction    | 6                      | 7                      |
| $Br(\omega \to \pi^+\pi^-\pi^0)$ | 0.8                | 0.8                    |
| Total                   | 9.4                    | 10.1                   |

0.8%. In the nominal fit, the radiative correction factor and the detection efficiency are determined under the assumption that the production of $e^+e^- \to Z_c(3900)^\pm \pi^\mp$ follows the $Y(4260)$ line shape. Using the line shape of $\sigma(e^+e^- \to Z_c(3900)^0\pi^0)$ measured in Ref. [4] as an alternative assumption, $\epsilon(1 + \delta)$ is increased by 6% for $\sqrt{s} = 4.23$ GeV and 7% for $\sqrt{s} = 4.26$ GeV. The change in $\epsilon(1 + \delta)$ is taken as a systematic uncertainty. The uncertainty of the vacuum polarization factor is taken from Ref. [5], and is negligible compared with other uncertainties. Assuming that all sources of systematic uncertainties are independent, the total errors are given by the quadratic sums.

To estimate the systematic uncertainties due to the fit procedure, we fit under different scenarios, and the upper limits obtained at the 90% C.L. for the $Z_c(3900)^\pm$ signal yield are summarized in Table II. The effect on the signal yield from the fit range is obtained by varying the fit range by $\pm 0.1$ GeV/$c^2$. The effect due to the choice of the background shape is estimated by changing the background shape from the ARGUS function to a second order polynomial (where the parameters of the polynomial are allowed to vary and the fit range is limited to [3.4, 4.08] GeV/$c^2$). The effect due to the resonance parameters of the $Z_c(3900)^\pm$ is estimated by varying the resonance parameters according to the results in Ref. [3]. The effect due to the mass resolution is estimated by increasing the resolution by 10% according to the comparison between the data and MC. The effect due to the mass-dependent efficiency curve is estimated by changing the efficiency curve to a constant function. We take the largest number of $Z_c(3900)^\pm$ events in the different scenarios as a conservative estimate of the upper limit: $N_{UL}^{1230} = 38.0$, $N_{UL}^{1260} = 18.8$. The resulting upper limits of the Born cross sections at $\sqrt{s} = 4.23$ and 4.26 GeV are determined to be 0.26 and 0.18 pb at the 90% C.L., respectively.

VI. SUMMARY AND DISCUSSION

In summary, based on data samples of 1092 pb$^{-1}$ at $\sqrt{s} = 4.23$ GeV and 826 pb$^{-1}$ at $\sqrt{s} = 4.26$ GeV collected with the BESIII detector operating at the BEPCII storage ring, a search is performed for the decay $Z_c(3900)^\pm \to \omega\pi^\pm$ in $e^+e^- \to \omega\pi^+\pi^-$. No $Z_c(3900)^\pm$ signal is observed. The corresponding upper limits on the Born cross section are set to be 0.26 and 0.18 pb at $\sqrt{s} = 4.23$ and 4.26 GeV, respectively. If we assume that the $Z_c(3900)^\pm$ observed in $e^+e^- \to J/\psi\pi^+\pi^-$ and $Z_c(3885)^\pm$ in $e^+e^- \to (D\bar{D}^*)^\pm \pi^\mp$ are the same particle, the decay width of $Z_c(3900)^\pm \to \omega\pi^\pm$ is estimated to be smaller than 0.2% of the $Z_c(3900)^\pm$ total width. As $\omega\pi$ is a typical light hadron decay mode of a $J^P = 1^+(1^+)$ resonance, the non-observation of $Z_c(3900)^\pm \to \omega\pi^\pm$ may indicate that the annihilation of $c\bar{c}$ in $Z_c(3900)^\pm$ is suppressed. Complementary to the searches for $Z_c(3900)$ production [15, 29], exploring new $Z_c(3900)$ decay modes may provide a significant input to clarify its dynamical origin.
