Abstract—Following the advent of the American Fuzzy Lop (AFL), fuzzing had a surge in popularity, and modern day fuzzers range from simple blackbox random input generators to complex whitebox concolic frameworks that are capable of deep program introspection. Web application fuzzers, however, did not benefit from the tremendous advancements in fuzzing for binary programs and remain largely blackbox in nature. This paper introduces BACKREST, a fully automated, model-based, coverage- and taint-driven fuzzer that uses its feedback loops to find more critical vulnerabilities, faster (speedups between 7.4× and 25.9×). To model the server-side of web applications, BACKREST automatically infers REST specifications through directed state-aware crawling. Comparing BACKREST against three other web fuzzers on five large (>500 KLOC) Node.js applications shows how it consistently achieves comparable coverage while reporting more vulnerabilities than state-of-the-art. Finally, using BACKREST, we uncovered nine 0-days, out of which six were not reported by any other fuzzer. All the 0-days have been disclosed and most are now public, including two in the highly popular Sequelize and MongoDB libraries.

Index Terms—fuzzing, greybox, coverage, taint analysis, REST

I. INTRODUCTION

Fuzzing encompasses techniques and tools to automatically identify vulnerabilities in programs by sending malformed or malicious inputs and monitoring abnormal behaviours. Nowadays, fuzzers come in three major shades: blackbox, greybox, and whitebox, according to how much visibility they have into the program internals [1]. Greybox fuzzing, which was made popular by the AFL fuzzer, combines blackbox with lightweight whitebox techniques, and have proven to be very effective at fuzzing programs that operate on binary input [2] [3] [4].

Most web application fuzzers that are used in practice are still blackbox [5] [6] [7] [8], and, despite decades of development, still struggle to automatically detect well studied vulnerabilities such as SQLi, and XSS [9]. As a result, security testing teams have to invest significant manual efforts into building models of the application and driving the fuzzer to trigger vulnerabilities. To overcome the limitations of current black-box web application fuzzers, and find more vulnerabilities automatically, new strategies must be investigated. To pave the way for the next generation of practical web application fuzzers, this paper first shows how REST models are a suitable abstraction for web applications and how adding lightweight coverage and taint feedback loops to a blackbox fuzzer can significantly improve performance and detection capabilities. Then, it highlights how the resulting BACKREST greybox fuzzer consistently detects more vulnerabilities than state-of-the-art. Finally, our evaluation reveals how BACKREST found nine 0-days, out of which six were missed by all the web application fuzzers we compared it against.

a) REST model inference: Model-based fuzzers, which use a model to impose constraints on input, dominate the web application fuzzing scene. Existing model-based web application fuzzers typically use dynamically captured traffic to derive a base model, which can be further enhanced manually [10] [7] [5]. As with any dynamic analysis, relying on captured traffic makes the quality of the model dependent on the quality of the traffic generator, be it a human being, a test suite, or a crawler. To navigate JavaScript-heavy applications and trigger a maximum number of endpoints, BACKREST directs a state-aware crawler towards JavaScript functions that trigger server-side interactions.

b) Feedback-driven: What makes greybox fuzzers so efficient is the feedback loop between the lightweight whitebox analysis components, and the blackbox input generator. BACKREST is the first web application fuzzer that can focus the fuzzing session on those areas of the application that haven’t been exercised yet (i.e. by using coverage feedback), and that have a higher chance of containing security vulnerabilities (i.e. by using taint feedback). Taint feedback in BACKREST further reports the type (e.g. SQLi, XSS, or command injection) of potential vulnerabilities, enabling BACKREST to aggressively fuzz a given endpoint with vulnerability-specific payloads, yielding tremendous performance improvements in practice.
aimed at governing interactions with web services, we make most modern client-side applications use to communicate with and conclude the paper. Sections VII and VIII present related work about them when they update their systems. Four of them have been tagged with high or critical severity, and two have been reported against the highly popular Sequelize (648 745 weekly downloads) and MongoDB (1 671 653 weekly downloads) libraries.

d) Contributions: This paper makes the following contributions:

• We show how REST APIs can effectively model the server-side of modern web applications, and quantify how coverage and taint feedback enhance coverage, performance, and vulnerability detection.

• We empirically evaluate BACKREST on five large (>500 KLOC) Node.js (JavaScript) web applications; a platform and language that are notoriously difficult to analyse, and under-represented in current security literature.

• We compare BACKREST against three state-of-the-art fuzzers (Arachni, Zap, and w3af) and open-source our test harness.

• We show how greybox fuzzing for web applications allows to detect severe 0-days that are missed by all the blackbox fuzzers we evaluated.

The rest of this paper is structured as follows. Section II presents our novel REST model inference technique. Section III and Section IV detail the BACKREST feedback-driven fuzzing algorithm and implementation, respectively. Section V evaluates BACKREST in terms of coverage, performance, and detected vulnerabilities and compares it against state-of-the-art web application fuzzers. Section VII presents and explains reported 0-days. Sections VII and VIII present related work and conclude the paper.

II. REST Model Inference

Web applications expose entry points in the form of URLs that clients can interact with via the HTTP protocol. However, the HTTP protocol specifies only how a client and a server can send and receive information over a network connection, not how to structure the interactions. Nowadays, representational state transfer (REST) is the de facto protocol that most modern client-side applications use to communicate with their backend server. While the REST protocol was primarily aimed at governing interactions with web services, we make the fundamental observation that client-server interactions in modern web applications can also be modelled with REST. Indeed, at its core, REST uses standard HTTP verbs, URLs, and request parameters to define and encapsulate client-server interactions, which, from our experience, is also what many modern web application frameworks do.

Despite the plethora of REST-related tools available, the task of creating an initial REST specification remains, however, largely manual. While tools exist to convert captured traffic into a REST specification, the burden of thoroughly exercising the application or augmenting the specification with missing information is still borne by developers. BACKREST alleviates this manual effort by extending a state-aware crawler designed for rich client-side JavaScript applications [11].

Modern web applications, and single-page ones in particular, implement complex and highly interactive functionalities on the client side. A recent Stack Overflow developer survey [12] shows that web applications are increasingly built using complex client-side frameworks, such as AngularJS [13] and React [14]. In fact, three out of five applications we evaluate in Section VII heavily use such frameworks. Using a state-aware crawler that can automatically navigate complex client-side frameworks allows BACKREST to discover server-side endpoints that can only be triggered through complex JavaScript interactions.

A. Motivating Example

Listing 1 shows an example definition from a Node.js Express application. At line 1, app refers to the programmatic web application object, and the delete method is used to define an HTTP DELETE entry point. The arguments to delete include the URL (i.e. "/users/" and path parameter (i.e. ":userId") of the entry point, and the callback function that will be executed on incoming requests. The callback function receives request (i.e. req) and response (i.e. res) objects as arguments, reads the userId path parameter at line 2, and removes the corresponding document from a collection in the database at line 3. The REST specification, in OpenAPI format [15], corresponding to the example entry point of Listing 1 is shown in Listing 2. Lines 2-4 define the "paths" entry that lists valid URL paths, where each path contains one entry per valid HTTP method. Lines 5-13 define the "parameters" object that lists the valid parameters for a given path and HTTP method. Specifically, line 7 defines the name of the parameter, line 8 specifies that it is a path parameter, line 9 specifies that the parameter is required, line 10 specifies that the expected type of the "userId" parameter is "string" and line 11 captures a concrete example value that was observed while crawling. Directing the crawler to exercise client-side code that will trigger server-side endpoints is, however, non-trivial and covered in the next section.

```javascript
app.delete("/users/:userId", (req, res) => {
  const id = req.params.userId;
  collection.remove({"id": id});
});
```

Listing 1. Example endpoint and its callback in Express

https://github.com/uqcyber/NodeJSFuzzing.
The state queue is prioritized either in a Depth First Search (DFS) or Breadth First Search (BFS) order, depending on the structure of the application. For instance, if an application is a traditional multi-page application and most of the endpoints would be triggered through static links, BFS can be more suitable, whereas a single-page application with workflows involving long sequences of client-side interactions, such as filling input elements and clicking buttons, would benefit more from a DFS traversal.

A state in the crawler includes the URL of the loaded page, its DOM tree, static links and valid events. To avoid revisiting same states, it compares the URLs and their DOM trees using a given threshold. As described in [11], it marks a state as previously visited if there exists a state in the cache that has the same URL and a DOM tree that is similar enough to the existing state. To compare the DOM trees, it parses them using the ElementTree XML [16] library and considers two trees to be in the same equivalence class if the number of different nodes does not exceed a threshold.

The crawler transitions between states by automatically triggering events that it extracts from HTML elements. It supports both statically and dynamically registered events, as well as customized event registration in frameworks. Determining the priority of events is one of the differentiating factors between state-aware crawlers. On the one hand, Crawljax [17], a well-known crawler for AJAX-driven applications randomly selects events from a state. On the other hand, Artemis [18], selects events that are more likely to increase code coverage. Feedex [19] instead prioritizes events that trigger user-specified workflows, such as adding an item. jAk [8] uses dynamic analysis to create a navigation graph with dynamically generated URLs and traces that contain runtime information for events. Its crawler then navigates the graph in an attempt to maximise server-side coverage. Similar to jAk, we also perform dynamic analysis to detect dynamically registered events that are difficult to detect statically and maximise coverage of server-side endpoints. Contrary to jAk, however, our crawler also uses a call graph analysis of the JavaScript code to compute a distance metric from event handler functions to target functions like XMLHttpRequest.send(), HTMLFormElement.submit(), or fetch and prioritize events that have smaller distances. This feature allows reaching target functions that are deeply embedded not only in the application code but also in the JavaScript frameworks and libraries that it uses. This prioritization strategy allows BACKREST to maximize coverage of JavaScript functions that trigger server-side endpoints. Listing 3 shows a hand-made and very simplified code-snippet that uses AngularJS for event handling. While the first button, B1 is a normal button and uses standard click event registration, the second button, B2 uses a custom event registration from the AngularJS framework. Our crawler can successfully correlate the customized click event for button B2 and prioritize B2 over B1 to call fetch("users/abc123") and trigger the server-side users/abc123 endpoint.

One of the challenges in dynamic analysis of web applications is performing authentication and correctly maintaining

B. Prioritised state-aware crawling for REST API inference

To improve responsiveness, modern web applications often transfer a large portion of their logic, including data preprocessing and validation to the client side. To prevent errors, frameworks implement checks on the server-side that validate the structure and to some extent the content of incoming requests. Fuzzing modern web applications thus require to produce requests that get past those initial server-side checks. To this end, BACKREST infers REST APIs from the requests generated by a state-aware crawler. Our crawler extends the one presented in [11] to automatically discover endpoints, parameters and types, and to produce concrete examples, as shown in Listing 2.

Figure 1 shows the architecture of the crawler in [11]. It combines prioritized link extraction (or spidering) and state-aware crawling to support both multi-page and single-page applications. It performs static link extraction and dynamic state processing using tasks that are managed in parallel. Given the URL of a running instance, the crawler’s task manager first creates a link extraction task for the top level url, where static links are extracted from HTML elements. Next, new link extraction tasks are created recursively for newly discovered links. At the same time, it creates new states for each extracted link and add them to a priority queue in a state crawl task.
the authenticated sessions. Our crawler provides support for a wide variety of authentication mechanisms, including Single Sign On, using a record-and-replay mechanism. We require the user to record the authentication once and use it to authenticate the application as many times as required. To verify whether a session is valid, we ask the user to provide an endpoint and pattern to look up in the response content once and before the crawling starts. For instance, for Juice-shop (see Section V), we verify the session by sending a GET request to the rest/user/whoami endpoint and check if "admin@juice-shop.op" is present in its response content periodically to make sure it is logged in.

We intercept the requests triggered by our crawler using a Man-In-The-Middle (MITM) proxy. Next, we process the recorded HTTP requests to infer a REST API specification automatically. Because we use a client-side crawler to trigger the endpoints, the recorded traffic contains valid headers and parameter values that are persisted in the REST API and reused in the fuzzing phase. These seed values can often prove invaluable to get past server-side value checks. Our API inference also aggregates concrete values to infer their types. Going back to the example in Listing 1, by automatically triggering delete requests to /users/ endpoint with an actual userId string value (e.g. abc123), our REST API inference adds userId path parameter with string type to the specification based on the observed userId values.

III. FEEDBACK-DRIVEN FUZZING

BACKREST builds on top of Sulley [20], a blackbox fuzzer with built-in networking support, and extends it with support for REST API parsing and fuzzing, as well as coverage and taint feedback. Figure 2 shows the high-level architecture of BACKREST. First, the application under test is crawled and a REST API is derived ①. Then, BACKREST is invoked on the generated REST API file ②. The API is then parsed ③ and broken down into low-level fuzzing code blocks ④. The type information included in the API file is used to select relevant mutation strategies (e.g. string, integer, JWT token, etc.). The fuzzing engine is then responsible for evaluating the individual fuzzing code blocks and reassembling them into a graph that will yield well-formed HTTP requests ⑤. The test case generator repeatedly traverses the graph to generate concrete HTTP requests, sends them to the application under test, and monitors taint and coverage feedback ⑥. The HTTP responses are dispatched to the analysis pipeline, which runs in a separate thread, to detect exploits, and are also stored as-is for logging purposes ⑦. Indicators of exploitation include the response time, the error code and error messages, reflected payloads, and taint feedback. Finally, the analysis results are aggregated and reported ⑧. To simplify our evaluation setup (sectionIV), we run BACKREST in deterministic mode, meaning that it always yields the same sequence of fuzzed HTTP requests for a given configuration.

A. Coverage Feedback

Coverage feedback, where the fuzzer uses online coverage information to guide the fuzzing session, was made popular by the AFL fuzzer [2]. Nowadays, most greybox fuzzers use coverage to guide their input generation engine towards producing input that will exercise newly covered code, or branches that will likely lead to new code [21, 22, 23, 24, 25, 3, 4]. Kelinci [26] ported AFL-style greybox fuzzing to Java programs by emulating AFL’s coverage analysis and using the AFL fuzzing engine as-is. JQF [27] instead combines QuickCheck-style testing [28] and feedback-directed fuzzing to support inputs with arbitrary data structures. The underlying assumption in AFL and all its derivatives is that targeting code that has not been thoroughly exercised increases the likelihood of triggering bugs and vulnerabilities. Empirical evidence suggests that this assumption holds true for many codebases. Furthermore, the simplicity and widespread availability of coverage analysis makes it suitable for applications written in a wide range of languages.

Compared to mutation-based greybox fuzzers like AFL, BACKREST uses coverage information differently. Where AFL-like fuzzers use coverage information to derive the next round of input, BACKREST uses coverage information to skip inputs in the test plan that would likely exercise well-covered code. From that perspective, BACKREST uses coverage information as a performance optimisation. Section III-C details how BACKREST uses coverage information.

B. Taint Feedback

Taint-directed fuzzing, where the fuzzer uses taint tracking to locate sections of input that influence values at key program locations (e.g. buffer index, or magic byte checks), was pioneered by Ganesh et al. with the BuzzFuzz fuzzer [29]. In recent years, many more taint-directed greybox fuzzers that build on the ideas of BuzzFuzz have been developed [30, 31, 32, 33, 34, 35].

BACKREST uses taint analysis in a different way. With the help of a lightweight dynamic taint inference analysis [36], it reports which input reaches security-sensitive program locations, and the type of vulnerability that could be triggered at each location. Armed with this information, BACKREST can prioritise payloads that are more likely to trigger potential vulnerabilities. Taint feedback thus enables BACKREST to zoom in payloads that are more likely to trigger vulnerabilities, which improves performance and detection capabilities. Taint feedback also improves detection capabilities in cases where exploitation cannot be easily detected in a blackbox manner. Finally, similar to coverage analysis, the relative simplicity of taint inference analysis makes it easy to port to a wide range of languages. The next section details how BACKREST uses taint feedback during fuzzing.

C. BACKREST Fuzzing Algorithm

Algorithm I shows the BACKREST fuzzing algorithm. It first builds a test plan, based on the REST model received as input (line 2). The test plan breaks the REST model into a
set of endpoints, lists “fuzzable” locations in each endpoint, and establishes a mutation schedule that specifies the values that are going to be injected at each location. Values are either cloned from the example fields, derived using mutations (omitted from Algorithm 1 for readability), or drawn from a pre-defined dictionary of payloads where vulnerability types map to a set of payloads. For example, the SQLi payload set contains strings like ‘ OR ’1’=’1’ -- , while the buffer overflow set contains very large strings and numbers.

Listing 4 shows an example of an endpoint definition with fuzzable locations in bold. From top to bottom, fuzzable locations include: the value of the userId parameter, where the parameter will be injected (e.g. path or request body), whether the parameter is required or optional, and the type of the parameter. Other locations are left untouched to preserve the core structure of the model and increase the likelihood of the request getting past shallow syntactic and semantic checks.

Once the test plan is built, BACKREST instruments the application for coverage and taint inference (lines 3-4 of Algorithm 1). Then, it starts iterating over the endpoints in the test plan (line 6). The fuzzer further sends a request for each (endpoint, location, payload) combination, collects the response, coverage and taint report, and increases its request counter by one (lines 13-15). If the request covers new code, the request counter is reset to zero, allowing the fuzzer to spend more time fuzzing that particular endpoint, location, and vulnerability type (lines 16-18). The vulnerability detector then inspects the response, searching for indicators of exploitation, and logs potential vulnerabilities (lines 19-22).

Because blackbox vulnerability detectors inspect the response only, they might miss cases where an input reached a

backREST brings together and builds on top of several existing components. The REST API inference component uses the state-aware crawler from [11] with an intercepting proxy [37] to generate and capture traffic dynamically. The REST API parser is derived from PySwagger [38] and the fuzzing infrastructure extends Sulley [20], with REST API processing support. For coverage instrumentation, we use the Istanbul library [39] and have added a middleware in benchmark applications to read the coverage object after each request, and inject a custom header to communicate coverage results back to the fuzzer. For taint feedback, backREST implements the Node.js taint analysis from [36] and adds our custom middleware to also communicate taint results back to the fuzzer. The taint analysis is itself built on top of the NodeProf.js instrumentation framework [40] that runs on the GraalVM [41] runtime.

V. Evaluation

In this section, we first evaluate how coverage and taint feedback increase the coverage, performance, or number of security-sensitive sink, without producing an observable side-effect. For example, a command injection vulnerability can be detected in a blackbox fashion only when an input triggers an observable side-effect, such as printing a fuzzer-controlled string, or making the application sleep for a certain amount of time. With taint feedback, however, the fuzzer is informed about: 1. whether parts of the input reached a sink, and 2. the vulnerability type associated with the sink. When the fuzzer is informed that an input reached a sink, it immediately jumps to the vulnerability type that matches that of the sink and starts sending payloads of that type only (lines 24-30). The idea behind this heuristic is that payloads that match the sink type have a higher chance of triggering observable side-effects to help confirm a potential vulnerability. Targeting specific vulnerability types further minimises the number of inputs required to trigger a vulnerability. Finally, if a given endpoint and location pair have been fuzzed for more than \( T \) requests (10 in our setup) without increasing coverage, the fuzzer jumps to the next vulnerability type (lines 31-33). The idea behind this heuristic, which we validated on our benchmarks (see subsection V-A), is that the likelihood of covering new code by fuzzing a given endpoint decreases with the number of requests. Promptly switching to payloads from a different vulnerability type reduces the total number of requests, thereby improving the overall performance.
vulnerabilities detected. The benchmark applications used for evaluation are listed in Table I. All experiments were run on a machine with 8 Intel Xeon E5-2690 2.60GHz processors and 32GB memory. Then, we compare BACKREST to three state-of-the-art web fuzzers. Finally, we present and explain the 0-days that BACKREST detected.

A. Feedback-driven fuzzing

Table II compares the total coverage and runtime achieved by enabling the coverage feedback loop only (column C) and combined with taint feedback (column CT) against the baseline blackbox fuzzer (column B). Table II also lists speedups for coverage and taint feedback loops compared to baseline. Coverage-wise, enabling the coverage feedback loop, which skips payloads of a given type after $T$ requests that did not increase coverage, achieves approximately the same coverage (i.e. $\pm 2\%$) in a much faster way (i.e. speedup between 7.0× and 10.9×). The slight variations in coverage can be explained by many different factors, such as the number of dropped requests, differences in scheduling and number of asynchronous computations, and differences in the application internal state. Indeed, the process of fuzzing the application under such a heavy load that exceptional behaviours become more common. Adding taint feedback on top of coverage feedback further decreases runtime, with speedups between 7.4× and 25.9×. The slightly lower coverage can be explained by the fact that taint feedback forces the fuzzer to skip entire payload types, resulting in lower input diversity and slightly lower total coverage. Finally, the size of the REST model for Apostrophe and the load that resulted from using the baseline fuzzer rendered the application unresponsive, and we killed the fuzzing session after 72 hours. Enabling taint feedback for Apostrophe almost halved the runtime compared to coverage feedback alone.

Figure 3 shows the cumulative coverage achieved by the baseline blackbox fuzzer on all applications but Apostrophe. For all applications, cumulative coverage evolves in a step-wise fashion (e.g. marked increases, followed by plateaus) where steps correspond to the fuzzer switching to a new endpoint. The plateaus that follow correspond to the fuzzer looping through its payload dictionary. These results support our coverage feedback heuristic, which is based on the assumption that the likelihood of covering new code by fuzzing a given endpoint decreases with the number of requests.

B. A note on server-side state modelling

Many studies have shown that state-aware crawling of the client-side yields better coverage [17, 18, 19, 8, 42], and our crawler is no exception. Very little is known, however, about the impact of state-aware fuzzing of the server-side. To our knowledge, RESTler [43] is the first study to investigate stateful fuzzing of web services. While the authors have found a positive correlation between stateful fuzzing and increases in coverage, we have not observed a similar effect on our benchmark applications. Similar to RESTler, we attempted to model the state of our benchmark applications by inferring dependencies between endpoints. Specifically, we used the approach from [44] to infer endpoint dependencies from crawling logs and then constrained the fuzzing schedule of BACKREST to honour them. This did not improve coverage for all but the Mongo-express application (data not shown).

In this particular case, manual inspection revealed that the inferred dependencies were quite intuitive (e.g. insert a document before deleting it) and easily configured.

C. Vulnerability detection

Table III shows the number of unique true positive bug reports with the baseline fuzzer (column B), with coverage feedback (column C), and further adding taint feedback (column CT). We manually reviewed all reported vulnerabilities and identified the root causes. Table III does not list false positives for space and readability reasons. The only false positives were an XSS in Nodegoat that was reported by all three variations, and an SQLi in Keystone that was reported with taint feedback only. Also note that Table III lists three types of vulnerabilities (SQLi, command injection, and XSS) and one type of attack (DoS). We opted to list DoS for readability reasons. Indeed, the root causes of DoS are highly diverse (out-of-memory, infinite loops, uncaught exception, etc.) making it difficult to list them all. From our experience, the most prominent root cause for DoS in Node.js are uncaught exceptions. Indeed, contrary to many web servers, the Node.js front-end that listens to incoming requests is single-threaded. Crashing the front-end thread with an uncaught exception thus crashes the entire Node.js process [45]. Interestingly, enabling coverage feedback has no impact on the detection of SQLi and command injection vulnerabilities, suggesting that this optimisation could be enabled at no cost. Enhancing the fuzzer with taint feedback, however, consistently detects as many or more SQLi and command injection vulnerabilities. This is explained by the fact that taint inference does not rely on client-observable side-effects of a payload to detect vulnerabilities. This is especially obvious for command injection vulnerabilities, which are detected with taint feedback only, for which observable side-effects are often hard to correlate to the root cause (e.g. slowdowns, internal server errors), compared to cross-site scripting, for example. Because the most critical injection flaws sit on the server-side of web applications, and are, by nature, harder to detect at the client side, the taint inference in BACKREST gives it a tremendous edge over blackbox fuzzers. Table III also shows, however, that some cross-site scripting and denial-of-service vulnerabilities are missed when coverage and taint feedback are enabled. First, all missed XSS are stored XSS. Indeed, through sheer brute force, the baseline fuzzer manages to send very specific payloads that exploit stored XSS vulnerabilities and trigger side-effects that can be observed at the client (e.g. reflecting the payload in another page), while coverage and taint feedback loops caused these specific payloads to be skipped. To reliably detect stored XSS, taint analysis would need to track taint flows through storage, which implies shadowing every storage device (i.e. databases and file
system) to store and propagate taint. This feature is beyond greybox fuzzing and is known to be tricky to implement, and costly from both time and memory perspectives [46]. Second, the missed denial-of-service vulnerabilities are due to: 1. a slow memory leak that requires several thousand requests to manifest in Apostrophe, and 2. a specific SQLite input that happened to be skipped with coverage and taint feedback.

a) Evaluating false negatives: In the context of a fuzzing session, false negatives are those vulnerabilities that are in the scope of a fuzzer, but that are missed. Accounting for false negatives requires an application with known vulnerabilities. The OWASP Nodegoat and Juice-Shop projects are deliberately vulnerable applications with seeded vulnerabilities. Both projects were built for educational purposes, and both have official solutions available, making it possible to evaluate false negatives. The solutions, however, list vulnerabilities from a penetration tester perspective; they list attack payloads, together with the error messages or screens they should lead to. For this reason, correlating the official solutions to BACKREST reports is not trivial. For example, the Juice-Shop solution reports several possible different SQL and NoSQL injection attacks. From a fuzzing perspective, however, all these attacks share the same two root causes: calling specific MongoDB and Sequelize query methods with unsanitised inputs. In other words, while the official solutions report different exploits, BACKREST groups them all under the same two vulnerability reports. For this study, we manually correlated all the SQLi, command injection, XSS, and DoS exploits in official solutions to vulnerabilities in the applications and found that BACKREST reports them all, achieving a recall of 100% for Nodegoat and Juice-Shop.

D. Comparison with state-of-the-art

In this section, we compare BACKREST against the arachni [47], w3af [6] and OWASP Zap [5] blackbox web application fuzzers. To minimise bias and ensure a fair evaluation, all three fuzzers were evaluated by an independent party who did not contribute and did not have access to BACKREST. All fuzzers were configured to scan for (No)SQLi, command injection, XSS, and DoS vulnerabilities. Significant care was also taken to configure all the fuzzers to authenticate into the applications and not log themselves out during a scan. Finally, after we discovered that the crawlers in arachni and w3af are fairly limited when it comes to navigating single-page web applications that heavily rely on client-side JavaScript, we evaluated these fuzzers with seed URLs from a Zap crawling...
Figure 4 shows the coverage that was achieved by the different fuzzers on the benchmark applications. BACKREST consistently achieves comparable coverage to other fuzzers. Table IV compares the number of bugs found by each fuzzer. For BACKREST, we report the bugs found with coverage and taint feedback only. Apart from denial-of-service, BACKREST consistently detects more vulnerabilities than other fuzzers, which we mostly attribute to the taint feedback loop. Indeed, while blackbox fuzzers can only observe the side-effects of their attacks through error codes and client-side inspection, BACKREST can determine with high precision if a payload reached a sensitive sink and report vulnerabilities that would otherwise be difficult to detect in a purely blackbox fashion. Furthermore, we confirmed through manual inspection that apart from DoS, BACKREST always reports a strict superset of the vulnerabilities reported by the other fuzzers. Deeper inspection revealed that the additional DoS found by Zap in Mongo-Express was due to a missing URL-encoded null byte payload (%00) in our payload dictionary.

It is very difficult to compare the performance of different web fuzzers, given the number of tunable parameters that each of them offers. For this reason, we focused our efforts on configuring them to maximise their detection power and did let them run until completion. Qualitatively, none of the fuzzer emerged as significantly faster or slower than the others. The runtime of BACKREST, as reported in Table II, is directly proportional to the size of the REST API, which explains the longer runtime on Apostrophe.

### E. Reported 0-days

Table V shows the 0-days that were identified in benchmark applications and their libraries. The taint only column shows whether a particular 0-day was reported with taint feedback only. Out of all the vulnerabilities reported in Table IV, nine translated into 0-days, out of which six were reported by BACKREST only. Several reasons explain why not all vulnerabilities translated to 0-day. First, recall that Nodegoat and Juice-Shop are deliberately insecure applications with seeded vulnerabilities. While BACKREST detected several of them, they are not 0-days. Interestingly, however, BACKREST did report non-seeded vulnerabilities in MarsDB, and Sequelize, which happen to be dependencies of Juice-Shop. Through
the fuzzing of Juice-Shop, BACKREST indeed triggered a command injection vulnerability in MarsDB and a denial-of-service in Sequelize. Second, the XSS that were reported in Apostrophe and Keystone are exploitable only in cases where the JSON response containing the XSS payload is processed and rendered in HTML. While we argue that returning JSON objects containing XSS payloads is a dangerous practice, developers decided otherwise and did not accept our reports as vulnerabilities. Third, Mongo-express is a database management console; it deliberately lets its users inject arbitrary content. Hence, NoSQLi in Mongo-express can be considered as a feature. Otherwise, the command injection and denial-of-service vulnerabilities in Mongo-express and its dependencies all translated into 0-days, and so did the denials-of-services in Apostrophe.

For readers who might not be familiar with the Node.js ecosystem, it is important to underline how the MongoDB and Sequelize libraries are core to millions of Node.js applications. At the time of writing, MongoDB had 1,671,653 weekly downloads while Sequelize had 648,745. By any standard, these libraries are extremely heavily used, and well exercised.

### VI. CASE STUDIES

In this section, we detail some of the 0-days we reported in Table V. We also explain some JavaScript constructs that might be puzzling to readers who are not familiar with the language. All the information presented in the following case studies is publicly available and a fix has been released for all but one of the vulnerabilities we present (MarsDB). In this particular case, the vulnerability report has been public since Nov 5th, 2019.

#### A. MarsDB command injection

MarsDB is an in-memory database that implements the MongoDB API. Listing 3 shows the command injection vulnerability in the MarsDB library that BACKREST uncovered. Attacker-controlled input is injected in the client application at line 3, through a request parameter (bolded). The client application then uses the unsanitised tainted input to build a MarsDB `find` query. In Node.js, long-running operations, such as querying a database, are executed asynchronously. In this example, calling the `find` method returns a JavaScript `promise` that will be resolved asynchronously. Calling the `then` method of a promise allows to register handler functions for cases where the promise is fulfilled (line 4) or rejected (line 6). The query eventually reaches the `where` function of the MarsDB library at line 9 as the `selectorValue` argument. That argument is then used at line 13 to dynamically create a new function from a string. From a security perspective, calling the `Function` constructor in JavaScript is roughly equivalent to calling the infamous `eval`; it dynamically creates a function from code supplied as a string. The newly created function is then called at line 16, which triggers the command injection vulnerability [48]. In this particular case, unless the payload is specifically crafted to: 1. generate a string that is valid JavaScript code, and 2. induce a side-effect that is observable from the client, it can be very difficult to detect this vulnerability in a purely blackbox manner. Thanks to taint feedback, BACKREST can detect the command injection as soon as any unsanitised input reaches the `Function` constructor at line 16.

#### B. Apostrophe DoS

Apostrophe is an enterprise content management system (CMS). Listing 6 shows a snippet of Apostrophe code that is vulnerable to a DoS attack. This code reads the `format` parameter of the request body, and checks if it is equal to “managePage” or “allIds” but misses a fallback option for cases where it is equal to neither. If this situation occurs, an uncaught exception is thrown, crashing the server [50].

#### C. Mongo-express command injections

Mongo-express is a MongoDB database management console. In versions prior to 0.54.0, it was calling an `eval`-like method with attacker-controllable input, leading to a command injection vulnerability. While BACKREST independently detected this vulnerability, it was concurrently reported days before our own disclosure [52]. Interestingly, BACKREST then revealed how the fix still enabled command injection. Indeed, the fix was to use the `mongo-db-query-parser` library to parse attacker-controlled input. The issue is that

| Codebase       | Vulnerability         | Found by      | Taint only | Severity | Disclosure |
|----------------|-----------------------|---------------|------------|----------|------------|
| MarsDB         | Command injection     | BACKREST      | ✓          | Critical | [52]       |
| Sequelize      | Denial-of-Service     | BACKREST      | —          | Moderate | [50]       |
| Apostrophe     | Denial-of-Service     | BACKREST      | —          | Low      | [51]       |
| Mongo-express  | Command injection     | BACKREST      | ✓          | Critical | [52]       |
| Mongo-express  | Denial-of-Service     | BACKREST, Zap, Arachni, w3af | Medium | [53] |
| Mongo-express  | Denial-of-Service     | Zap, Arachni, w3af | TBA | TBA |
| MongoDB-query-parser | Command injection | BACKREST     | ✓          | Critical | [51]       |
| MongoDB        | Denial-of-Service     | BACKREST, Zap | High      | [53]       |

† BACKREST independently and concurrently found the same vulnerability
// Juice-Shop code
// Implements the /rest/track-order/{id} route
db.orders.find({ $where: "this.orderId === "+ req.params.id + "+" }).then(
  order => { ... },
  err => { ... }
);

// MarsDB code
$where: function(selectorValue, matcher) {
  matcher._recordPathUsed('');
  matcher._hasWhere = true;
  if (!(selectorValue instanceof Function)) {
    selectorValue = Function('obj', 'return ' + selectorValue);
  }
  return function(doc) {
    return {result: selectorValue.call(doc, doc)};
  };
};

Listing 5. Command injection vulnerability in MarsDB

self.routes.list = function(req, res) {
  ...
  if (req.body.format === 'managePage') {
    ...
  } else if (req.body.format === 'allIds') {
    ...
  }
  return self.listResponse(req, res, err, results);
};

Listing 6. Denial-of-Service (DoS) vulnerability in Apostrophe

the library is using eval itself. Thanks to taint feedback, BACKREST detected that tainted input was still flowing to an eval call, which we disclosed [54].

D. Sequelize DoS

Sequelize is a Node.js Object-Relational Mapper (ORM) for Postgres, MySQL, MariaDB, SQLite and Microsoft SQL Server. The code in [Listing 7] is vulnerable to a DoS attack that crashes the Node.js server with an uncaught exception. First, an attacker-controllable SQL query is passed as the sql argument to the run function that executes SQL queries at line 1. The tainted query is assigned to various variables, the query is executed, and after its execution is eventually searched for the string "sqlite_master" at line 7, which is a special table in SQLite. If the search is successful, the query is then searched for the string "SELECT sql FROM sqlite_master WHERE tbl_name". If this search is unsuccessful and the query returned a results object that is not undefined (line 14), the map method is called on the results object at line 16. This is where the DoS vulnerability lies. If the results object is not an array, it likely won’t have a map method in its prototype chain, which will throw an uncaught TypeError and crash the Node.js process [49]. In summary, any request that includes the string "sqlite_master", but not "SELECT sql FROM sqlite_master WHERE tbl_name", will crash the underlying Node.js process.

E. MongoDB DoS

MongoDB is a document-based NoSQL database with drivers in several languages. [Listing 8] shows a snippet from the MongoDB driver that has a DoS vulnerability. This code gets executed when new collections are created in a MongoDB database. If the name of the collection to be created is attacker-controllable, and the attacker supplies an invalid collection name, the call to the Collection constructor at line 10 fails and throws an uncaught MongoError that crashes the Node.js process [55]. The taint feedback loop quickly reports that a tainted collection name flows to the Collection constructor, enabling BACKREST to trigger the vulnerability faster.

VII. RELATED WORK

a) Web application modelling: Modelling for web applications has a long and rich history in the software engineering and testing communities. Modelling methods broadly fall into three main categories: graph-based, UML-based, and FSM-based. Graph-based approaches focus on extracting navigational graphs from web applications and applying graph-based algorithms (e.g. strongly connected components, dominators) to gain a better understanding of the application [56][57]. UML-based approaches further capture the interactions and flows of data between the different components of a web application (e.g. web pages, databases, and server) as a UML...
run(sql, parameters) {
  this.sql = sql;
  ...
  const query = this;
  function afterExecute(err, results) {
    ...
    if (query.sql.indexOf('sqlite_master') !== -1) {
      if (query.sql.indexOf('SELECT sql FROM sqlite_master WHERE tbl_name') !== -1) {
        result = results;
        if (result && result[0] && result[0].sql.indexOf('CONSTRAINT') !== -1) {
          result = query.parseConstraintsFromSql(results[0].sql);
        } else if (results !== undefined) {
          // Throws a TypeError if results is not an array.
          result = results.map(resultSet => resultSet.name);
        } else {
          result = {};
        }
      } else if (results !== undefined) {
        // Throws an uncaught MongoError if the name argument is invalid
        new Collection(db, db.s.topology, db.s.databaseName, name, db.s.pkFactory, options);
      }
    }
    ...}
  }
}

Listing 7. Denial-of-Service (DoS) vulnerability in Sequelize

function createCollection(db, name, options, callback) {
  ...
  executeCommand(db, cmd, finalOptions,
  err => {
    if (err) return handleCallback(callback, err);
    handleCallback(
      callback,
      null,
      // Throws an uncaught MongoError if the name argument is invalid
      new Collection(db, db.s.topology, db.s.databaseName, name, db.s.pkFactory, options)
    );
  });
  ...
}

Listing 8. Denial-of-Service (DoS) vulnerability in MongoDB

model [58, 56, 59]. To facilitate automated test case generation, FSM-based approaches instead cluster an application into sub-systems, model each with a finite-state machine and unify them into a hierarchy of FSMs [60]. All these approaches were designed to model stateful web applications, which were the norm back in the early 2000s. Since then, web development practices evolved, developers realised that building server-side applications that are as stateless as possible improves maintainability, and the REST protocol, which encourages statelessness, gained significant popularity.

b) Grammar inference: Automated learning of grammars from inputs is a complementary and very promising research area [61, 62, 63]. To efficiently learn a grammar from inputs, however, current approaches either require: 1. very large datasets of input to learn from [61]; 2. highly-structured parser code that reflects the structure of the underlying grammar [62]; or 3. a reliable oracle to determine whether a given input is well-formed [63]. Unfortunately, very few web applications meet any of these criteria, making model inference the only viable alternative. Compared to synthesised grammars, REST models are also easier to interpret.

c) Model-based fuzzing: Model-based fuzzing derives input from a user-supplied [64, 43], or inferred [65, 66, 67, 68, 42] model. Contrary to grammar-based fuzzing [69, 70, 71], input generation in model-based fuzzing is not constrained by a context-free grammar. While grammar-based fuzzers generally excel at fuzzing language parsers, model-based fuzzers are often better suited for higher-level programs with more weakly-structured input.

d) REST-based fuzzing: Most closely related to our work are REST-based fuzzers. In recent years, many HTTP fuzzers have been extended to support REST specifications [72, 73, 74, 75, 76], but received comparatively little attention from the academic community. RESTler [43] is the exception. It uses a user-supplied REST specification as a model for fuzzing REST-based services in a blackbox manner. To better handle stateful services, RESTler enriches its model with inferred dependencies between endpoints. As we highlighted in subsection V-B, we haven’t found endpoint dependency inference to have a significant impact on the coverage of all
but one of our benchmark applications. For Mongo-express, we found that the inferred dependencies were trivial, easily configurable and did not justify the added complexity.

e) Taint-based fuzzing: Taint-based fuzzing uses dynamic taint analysis to monitor the flow of attacker-controlled values in the program under test and to guide the fuzzer [29, 30, 31]. Wang et al. [32, 33] use taint analysis to identify the parts of an input that are compared against checksums. Similarly, Haller et al. use taint analysis to identify inputs that can trigger buffer overflow vulnerabilities [34], while Vuzzer [35] uses it to identify parts of an input that are compared against magic bytes or that trigger error code. Taint analysis has also been used to map input to the parser code that processes it and to infer an input grammar [70].

More closely related to our work, the KameleonFuzz tool [68] uses taint inference on the client-side of web applications to detect reflected inputs and exploit cross-site scripting vulnerabilities. Black Widow [77] implements several stateful crawling strategies in combination with taint inference to detect stored and reflected cross-site scripting vulnerabilities in PHP applications.

f) Web application security scanning: The process of exercising an application with automatically generated malformed, or malicious input, which is nowadays known as fuzzing, is not new, and is also known as security scanning, attack generation, or vulnerability testing in the web community. Whitebox security scanning tools include the QED tool [78] that uses goal-directed model checking to generate SQLi and XSS attacks for Java web applications. The seminal Ardilla paper [46] presented a whitebox technique to generate SQLi and XSS attacks using taint analysis, symbolic databases, and an attack pattern library. Ardilla was implemented using a modified PHP interpreter, tying it to a specific version of an attack pattern library. The Pixy tool [90] then showed how static taint analysis could be used to detect injection vulnerabilities, such as SQLi and XSS, in Java web applications [89]. The Pixy tool [90] then showed how static taint analysis could be used to detect web vulnerabilities in PHP web applications. The AMNESIA tool [91] introduced the idea of modelling SQL queries with static analysis and checking them against the model at runtime. This idea was further formalised by Su et al. [92], applied to XSS detection [93] and is still used nowadays to counter injection attacks in Node.js applications [94].

h) JavaScript vulnerability detection: As Web 2.0 technologies gained in popularity, the client-side of web applications became richer, and researchers started investigating the JavaScript code that runs in our browsers. It became quickly obvious, however, that existing static analysis techniques could not be easily ported to JavaScript, and that dynamic techniques were better suited for highly dynamic JavaScript code [95]. Dynamic taint analysis thus started to gain popularity, and was particularly successful at detecting client-side DOM-based XSS vulnerabilities [96, 97]. In the meantime, in 2009, the first release of Node.js, which brings JavaScript to the server-side, came out, and is now powering millions of web applications worldwide. Despite its popularity, however, the Node.js platform comparatively received little attention from the security community [45, 98, 99], with only two studies addressing injection vulnerabilities [94, 83].

VIII. Conclusion

We presented BACKREST, the first fully automated model-based, coverage- and taint-driven greybox fuzzer for web applications. BACKREST guides a state-aware crawler to automatically infer REST APIs, and uses coverage feedback to avoid fuzzing thoroughly covered code. BACKREST makes a novel use of taint feedback to focus the fuzzing session on likely vulnerable areas, guide payload generation, and detect more vulnerabilities. Compared to a baseline version without taint and coverage feedback, BACKREST achieved speedups ranging from 7.4× to 25.9×. BACKREST also consistently detected more (No)SQLi, command injection, and XSS vulnerabilities than three state-of-the-art web fuzzers and detected six 0-days that were missed by all other fuzzers.

By extending a blackbox web application fuzzer with lightweight whitebox analysis, we showed how greybox fuzzing can detect more vulnerabilities faster. We hope that our study will trigger further research in this area and encourage researchers to develop lightweight greybox fuzzers for web applications written in languages that have received little attention so far, like Python and Ruby.
