Transcriptional Mechanisms of Drug Addiction

Eric J. Nestler
Fishberg Department of Neuroscience and Friedman Brain Institute, Mount Sinai School of Medicine, New York, USA

Regulation of gene expression is considered a plausible mechanism of drug addiction given the stability of behavioral abnormalities that define an addicted state. Numerous transcription factors, proteins that bind to regulatory regions of specific genes and thereby control levels of their expression, have been implicated in the addiction process over the past decade or two. Here we review the growing evidence for the role played by several prominent transcription factors, including a Fos family protein (ΔFosB), cAMP response element binding protein (CREB), and nuclear factor kappa B (NFκB), among several others, in drug addiction. As will be seen, each factor displays very different regulation by drugs of abuse within the brain's reward circuitry, and in turn mediates distinct aspects of the addiction phenotype. Current efforts are geared toward understanding the range of target genes through which these transcription factors produce their functional effects and the underlying molecular mechanisms involved. This work promises to reveal fundamentally new insight into the molecular basis of addiction, which will contribute to improved diagnostic tests and therapeutics for addictive disorders.

KEY WORDS: Transcription factors; Nucleus accumbens; Ventral tegmental area; Orbitofrontal cortex; Chromatin remodeling; Epigenetics.

INTRODUCTION

The study of transcriptional mechanisms of addiction is based on the hypothesis that regulation of gene expression is one important mechanism by which chronic exposure to a drug of abuse causes long-lasting changes in the brain that underlie the behavioral abnormalities that define a state of addiction. A corollary of this hypothesis is that changes induced in the functioning of several neurotransmitter systems, and in the morphology of certain neuronal cell types in the brain, by chronic drug administration are mediated in part via changes in gene expression.

Of course, not all drug-induced neural and behavioral plasticity is mediated at the level of gene expression, as we know the crucial contributions of translational and post-translational modifications and protein trafficking in addiction-related phenomena. On the other hand, regulation of gene expression is one central mechanism and likely to be particularly crucial for the life-long abnormalities that characterize addiction. Indeed, transcriptional regulation provides a template on top of which these other mechanisms operate.

Work over the past ~15 years has provided increasing evidence for a role of gene expression in drug addiction, as several transcription factors - proteins that bind to specific responses elements in the promoter regions of target genes and regulate those genes’ expression - have been implicated in drug action. According to this scheme, shown in Fig. 1, drugs of abuse, via their initial actions at the synapse, produce changes within neurons that signal to the nucleus and regulate the activity of numerous transcription factors and many other types of transcriptional regulatory proteins. A These nuclear changes gradually and progressively build with repeated drug exposure and underlie stable changes in the expression of specific target genes which, in turn, contribute to the lasting changes in neural function that maintain a state of addiction.

This review focuses on several transcription factors, which have been shown to play important roles in addiction. We focus further on drug-regulated transcription factors within the brain’s reward circuitry, areas of brain that normally regulate an individual’s responses to natural rewards (e.g., food, sex, social interaction), but are corrupted by chronic drug exposure to cause addiction. This brain reward circuitry includes dopaminergic neu-
Transcriptional Mechanisms of Drug Addiction

Fig. 1. Transcriptional actions of drugs of abuse. Although drugs of abuse act initially on their immediate protein targets at the synapse, their long-term functional effects are mediated in part via regulation of downstream signaling pathways which converge on the cell nucleus. Here, drug regulation of transcription factors leads to the stable regulation of specific target genes and to the lasting behavioral abnormalities that characterize addiction.

rons in the ventral tegmental area of the midbrain and the several regions of limbic forebrain they innervate, including nucleus accumbens (ventral striatum), prefrontal cortex, amygdala, and hippocampus, among others. As will be seen, the vast majority of research on transcriptional mechanisms of addiction to date has concentrated on the nucleus accumbens.

\( \Delta FosB \)

\( \Delta FosB \) is encoded by the FosB gene and shares homology with other Fos family transcription factors, which include c-Fos, FosB, Fra1, and Fra2. These Fos family proteins heterodimerize with Jun family proteins (c-Jun, JunB, or JunD) to form active activator protein-1 (AP1) transcription factors that bind to AP1 sites present in the promoters of certain genes to regulate their transcription. These Fos family proteins are induced rapidly and transiently in specific brain regions after acute administration of many drugs of abuse (Fig. 2). These responses are seen most prominently in nucleus accumbens and dorsal striatum, but also seen in several other brain areas. All of these Fos family proteins, however, are highly unstable and return to basal levels within hours of drug administration.

Very different responses are seen after chronic administration of drugs of abuse (Fig. 2). Biochemically modified isoforms of \( \Delta FosB \) (M, 35-37 kD) accumulate within the same brain regions after repeated drug exposure, whereas all Fos family members show tolerance (that is, reduced induction compared with initial drug exposures). Such accumulation of \( \Delta FosB \) has been observed for virtually all drugs of abuse, although different drugs differ somewhat in the relative degree of induction seen in nucleus accumbens core vs. shell, dorsal striatum, and other brain regions. At least for some drugs of abuse, induction of \( \Delta FosB \) appears selective for the dynorphin-containing subset of medium spiny neurons - those that predominantly express D1 dopamine receptors - within striatal regions. The 35-37 kD isoforms of \( \Delta FosB \) dimerize predominantly with JunD to form an active and long-lasting AP-1 complex within these brain regions, although there is some evidence from in vitro studies that \( \Delta FosB \) may form homodimers. Drug induction of \( \Delta FosB \) in the nucleus accumbens seems to be a response to the pharmacological properties of the drug per se and not related to volitional drug intake, since animals that self-administer cocaine or receive yoked drug injections show equivalent induction of this transcription factor in this brain region.

In contrast, \( \Delta FosB \) induction in certain other regions, for example, orbitofrontal cortex, requires volitional drug administration. The 35-37 kD \( \Delta FosB \) isoforms accumulate with chronic drug exposure due to their extraordinarily long half-lives. As a result of its stability, the \( \Delta FosB \) protein persists in neurons for at least several weeks after cessation of drug exposure. We now know that this stability is due to two factors: 1) the absence in \( \Delta FosB \) of two degron
Domains, which are present at the C-terminus of full length FosB and all other Fos family proteins and target those proteins to rapid degradation, and 2) the phosphorylation of ΔFosB at its N-terminus by casein kinase 2 and perhaps other protein kinases. The stability of the ΔFosB isoforms provides a novel molecular mechanism by which drug-induced changes in gene expression can persist despite relatively long periods of drug withdrawal. We have, therefore, proposed that ΔFosB functions as a sustained “molecular switch” that helps initiate and then maintain an addicted state.

**Role in Addiction**

Insight into the role of ΔFosB in drug addiction has come largely from the study of bitransgenic mice in which ΔFosB can be induced selectively within the nucleus accumbens and dorsal striatum of adult animals. Importantly, these mice overexpress ΔFosB selectively in the dynorphin-containing medium spiny neurons, where the drugs are believed to induce the protein. ΔFosB-overexpressing mice show augmented locomotor responses to cocaine after acute and chronic administration. They also show enhanced sensitivity to the rewarding effects of cocaine and of morphine in place conditioning assays.

---

**Fig. 2.** Distinct temporal properties of drug regulation of ΔFosB vs. CREB. (A) ΔFosB. The top graph shows several waves of Fos family proteins (comprised of c-Fos, FosB, ΔFosB (33 kD isoform), Fra1, Fra2) induced in nucleus accumbens by acute administration of a drug of abuse. Also induced are biochemically modified isoforms of ΔFosB (35-37 kD); they are induced at low levels by acute drug administration, but persist in brain for long periods due to their stability. The lower graph shows that with repeated (e.g., twice daily) drug administration, each acute stimulus induces a low level of the stable ΔFosB isoforms. This is indicated by the lower set of overlapping lines, which indicate ΔFosB induced by each acute stimulus. The result is a gradual increase in the total levels of ΔFosB with repeated stimuli during a course of chronic treatment. This is indicated by the increasing stepped line in the graph. (B) CREB. Activation of CRE transcriptional activity, mediated via phosphorylation and activation of CREB and possibly via the induction of certain ATFs, occurs rapidly and transiently in nucleus accumbens in response to acute drug administration. This “peak and trough” pattern of activation persists through chronic drug exposure, with CRE transcription levels reverting to normal within 1-2 days of drug withdrawal.
and self-administer lower doses of cocaine, and work harder for cocaine, than littermates that do not overexpress ΔFosB.19) Additionally, ΔFosB overexpression in nucleus accumbens exaggerates the development of opiate physical dependence and promotes opiate analgesic tolerance. After treatment is longer, ΔFosB expressing mice are normal in several other behavioral domains, including spatial learning as assessed in the Morris water maze.17) Specific targeting of ΔFosB overexpression to the nucleus accumbens, by use of viral-mediated gene transfer, has yielded equivalent data.19

In contrast, targeting ΔFosB expression to the enkephalin-containing medium spiny neurons in nucleus accumbens and dorsal striatum (those that predominantly express D2 dopamine receptors) in different lines of bitransgenic mice fail to show most of these behavioral phenotypes.19) In contrast to overexpression of ΔFosB, overexpression of a mutant Jun protein (ΔcJun or ΔJunD) - which functions as a dominant negative antagonist of AP1 mediated transcription - by use of bitransgenic mice or viral-mediated gene transfer, produces the opposite behavioral effects.14,19,21) These data indicate that induction of ΔFosB in dynorphin-containing medium spiny neurons of the nucleus accumbens increases an animal’s sensitivity to cocaine and other drugs of abuse, and may represent a mechanism for relatively prolonged sensitization to the drugs.

The role played by ΔFosB induction in other brain regions is less well understood. Recent studies have shown that ΔFosB induction in orbitofrontal cortex mediates tolerance to some of the cognitive-disrupting effects of acute cocaine exposure, which might serve to further promote drug intake.12,22)

ΔFosB Target Genes

Since ΔFosB is a transcription factor, it presumably produces this interesting behavioral phenotype in nucleus accumbens by enhancing or repressing expression of other genes. Using our inducible, bitransgenic mice that overexpress ΔFosB or its dominant negative ΔcJun, and analyzing gene expression on Affymetrix chips, we demonstrated that - in the nucleus accumbens in vivo - ΔFosB functions primarily as a transcriptional activator, while it serves as a repressor for a smaller subset of genes.19) This study also demonstrated the dominant role of ΔFosB in mediating the genomic effects of cocaine: ΔFosB is implicated in close to one-quarter of all genes influenced in nucleus accumbens by chronic cocaine.

This genome-wide approach, along with studies of several candidate genes in parallel, have established several target genes of ΔFosB that contribute to its behavioral phenotype. One candidate gene is GluA2, an AMPA glutamate receptor subunit, which is induced in nucleus accumbens by ΔFosB.17) Since GluA2-containing AMPA channels have a lower overall conductance compared to AMPA channels that do not contain this subunit, the cocaine- and ΔFosB-mediated upregulation of GluA2 in nucleus accumbens could account, at least in part, for the reduced glutamatergic responses seen in these neurons after chronic drug exposure.23)

Another candidate target gene of ΔFosB in nucleus accumbens is the opioid peptide, dynorphin. Recall that ΔFosB appears to be induced by drugs of abuse specifically in dynorphin-producing cells in this brain region. Drugs of abuse have complex effects on dynorphin expression, with increases or decreases seen depending on the treatment conditions used. We have shown that induction of ΔFosB represses dynorphin gene expression in nucleus accumbens.19) Dynorphin is thought to activate κ opioid receptors on ventral tegmental area (VTA) dopamine neurons and inhibit dopaminergic transmission and thereby downregulate reward mechanisms.24,25) Hence, ΔFosB repression of dynorphin expression could contribute to the enhancement of reward mechanisms mediated by this transcription factor. There is now direct evidence supporting the involvement of dynorphin gene repression in ΔFosB’s behavioral phenotype.19)

Still additional target genes have been identified. ΔFosB represses the c-Fos gene which helps create the molecular switch - from induction of several short-lived Fos family proteins after acute drug exposure to the predominant accumulation of ΔFosB after chronic drug exposure - cited earlier.19) In contrast, cyclin-dependent kinase-5 (Cdk5) is induced in the nucleus accumbens by chronic cocaine, an effect that we have shown is mediated via ΔFosB.18,21,26) Cdk5 is an important target of ΔFosB since its expression has been directly linked to increases in dendritic spine density of nucleus accumbens medium spiny neurons.27,28) In the nucleus accumbens that are associated with chronic cocaine administration.29,30) Indeed, ΔFosB induction has been shown more recently to be both necessary and sufficient for cocaine-induced dendritic spine growth.31)

More recently, we have used chromatin immunoprecipitation (ChiP) followed by promoter chip (ChiP-chip) or by deep sequencing (ChiP-seq) to further identify ΔFosB target genes.32) These studies, along with the DNA expression arrays cited earlier, are providing a rich list of many additional genes that may be targeted - directly or indirectly - by ΔFosB. Among these genes are additional neurotransmitter receptors, proteins involved in pre- and postsynaptic func-
tion, many types of ion channels and intracellular signaling proteins, proteins that regulate the neuronal cytoskeleton and cell growth, and numerous proteins that regulate chromatin structure. Further work is needed to confirm each of these numerous proteins as bona fide targets of cocaine acting through ΔFosB and to establish the precise role that each protein plays in mediating the complex neural and behavioral aspects of cocaine action.

**CREB**

Cyclic AMP response element binding protein (CREB) is one of the most studied transcription factors in neuroscience and has been implicated in diverse aspects of neural plasticity. It forms homodimers that can bind to genes at cyclic AMP response elements (CREs), but primarily activates transcription after it has been phosphorylated at Ser133 (by any of several protein kinases), which allows binding to CRE sites. Recent studies have implicated CREB activity in the nucleus accumbens medium spiny neurons. Possible differences between dynorphin and enkephalin neurons have not yet been explored. The observation that viral-mediated overexpression of a K⁺ channel subunit in the nucleus accumbens, which decreases medium spiny neuron excitability, enhances locomotor responses to cocaine suggests that CREB acts as a break on behavioral sensitization to cocaine by upregulating neuron excitability.

Drugs of abuse activate CREB in several brain regions beyond the nucleus accumbens. One example is the ventral tegmental area, where chronic administration of cocaine or opiates activates CREB within dopaminergic and non-dopaminergic neurons. This effect seems to promote or attenuate the rewarding responses of drugs of abuse depending on the subregion of the ventral tegmental area affected.

Numerous target genes for CREB have been identified, through both open-ended and candidate gene approaches, which mediate these and other effects on nucleus accumbens medium spiny neurons and the resulting CREB behavioral phenotype. Prominent examples include the opioid peptide dynorphin, which feeds back and suppresses dopaminergic signaling to the nucleus accumbens as stated earlier. Also implicated are certain glutamate receptor subunits, such as the GluA1 AMPA subunit and GluN2B NMDA subunit, as well as K⁺ and Na⁺ ion channel subunits, which together would be expected to control nucleus accumbens cell excitability. BDNF is still another target gene for CREB in nucleus accumbens, and it too is implicated in mediating the CREB behavioral phenotype. CREB induction also has been shown to contribute to cocaine’s induction of dendritic spines on nucleus accumbens medium spiny neurons.

CREB is just one of several related proteins that bind CREs and regulate transcription of target genes. Several products of the cyclic AMP response element modulator (CREM) gene regulate CRE-mediated transcription. Some of the products (e.g., CREM) are transcriptional activators, whereas others (e.g., ICER or inducible cyclic AMP repressor) function as endogenous dominant negative antagonists. In addition, several activating transcription factors (ATFs) can influence gene expression in part by binding to CRE sites. Recent studies have implicated
these various transcription factors in drug responses. Amphetamine induces ICER expression in nucleus accumbens, and overexpression of ICER in this region, by use of viral-mediated gene transfer, increases an animal’s sensitivity to the behavioral effects of the drug. This is consistent with findings, cited above, that local overexpression of dominant negative CREB mutants or local knockdown of CREB exerts similar effects. Amphetamine also induces ATF2, ATF3, and ATF4 in nucleus accumbens, while no effect is seen for ATF1 or CREM. ATF2 overexpression in this region, like that of ICER, increases behavioral responses to amphetamine, while ATF3 or ATF4 overexpression has the opposite effect. Very little is known about the target genes for these various CREB family proteins, an important direction for future research.

NFκB

Nuclear factor-κB (NFκB), a transcription factor that is rapidly activated by diverse stimuli, is best studied for its role in inflammation and immune responses. It has more recently been shown to be important in synaptic plasticity and memory. NFκB is induced in the nucleus accumbens by repeated cocaine administration, where it is required for cocaine’s induction of dendritic spines of nucleus accumbens medium spiny neurons. Such induction of NFκB contributes to sensitization to the rewarding effects of the drug. A major goal of current research is to identify the target genes through which NFκB causes this cellular and behavioral plasticity.

Interestingly, cocaine induction of NFκB is mediated via ΔFosB: ΔFosB overexpression in nucleus accumbens induces NFκB, while overexpression of the Δc-Jun dominant negative blocks cocaine induction of the transcription factor. Regulation of NFκB by ΔFosB illustrates the complex transcriptional cascades involved in drug action. As well, NFκB has been implicated in some of the neurotoxic effects of methamphetamine in striatal regions. The role of NFκB in medium spiny neuron spinogenesis has recently been extended to stress and depression models, a finding of particular importance considering the comorbidity of depression and addiction, and the well-studied phenomenon of stress-induced relapse to drug abuse.

MEF2

Myocyte enhancing factor-2 (MEF2) was discovered for its role in controlling cardiac myogenesis. More recently, MEF2 has been implicated in brain function. Multiple MEF2 isoforms are expressed in brain, including in nucleus accumbens medium spiny neurons, where they form homo- and heterodimers that can activate or repress gene transcription depending on the nature of the proteins they recruit. Recent work outlines a possible mechanism by which chronic cocaine suppresses MEF2 activity in the nucleus accumbens in part through a D1 receptor-cAMP-dependent inhibition of calcineurin, a Ca2+-dependent protein phosphatase. Cocaine regulation of Cdk5, which is also a target for cocaine and ΔFosB as stated earlier, may be involved as well. This reduction in MEF2 activity is required for cocaine induction of dendritic spines on medium spiny neurons. An important focus of current work is to identify the target genes through MEF2 produces this effect.

FUTURE DIRECTIONS

The transcription factors discussed above are just a few of many that have been studied over the years in addiction models. Others implicated in addiction include the glucocorticoid receptor, nucleus accumbens 1 transcription factor (NAC1), early growth response factors (EGRs), and signal transducers and activators of transcription (STATs). As just one example, the glucocorticoid receptor is required in dopaminergic neurons for cocaine seeking. The goal of future research is to obtain a more complete view of the transcription factors induced in nucleus accumbens and other brain reward regions in response to chronic exposure to drugs of abuse and to define the range of target genes they influence to contribute to the behavioral phenotype of addiction.

The other major goal of future research is to delineate the precise molecular steps by which these various transcription factors regulate their target genes. Thus, we now know that transcription factors control gene expression by recruiting to their target genes a series of co-activator or co-repressor proteins which together regulate the structure of chromatin around the genes and the subsequent recruitment of the RNA polymerase II complex which catalyzes transcription. For example, recent research has demonstrated that the ability of ΔFosB to induce the cdk5 gene occurs in concert with the recruitment of a histone acetyltransferase and related chromatin remodeling proteins to the gene. In contrast, the ability of ΔFosB to repress the c-Fos gene occurs in concert with the recruitment of a histone deacetylase and presumably several other repressive proteins such as a repressive histone methyltransferase (Fig. 3). Given that hundreds of chroma-
Mechanisms that underlie addiction. Dramatic advances in our understanding of transcription factors, this information will provide an increasingly complete template that can be used to guide drug discovery efforts. It is hoped that new medication treatments will be developed based on these dramatic advances in our understanding of transcription mechanisms that underlie addiction.
