Motivating the Rules of the Game for Adversarial Example Research

Abstract

Advances in machine learning have led to broad deployment of systems with impressive performance on important problems. Nonetheless, these systems can be induced to make errors on data that are surprisingly similar to examples the learned system handles correctly. The existence of these errors raises a variety of questions about out-of-sample generalization and whether bad actors might use such examples to abuse deployed systems. As a result of these security concerns, there has been a flurry of recent papers proposing algorithms to defend against such malicious perturbations of correctly handled examples. It is unclear how such misclassifications represent a different kind of security problem than other errors, or even other attacker-produced examples that have no specific relationship to an uncorrupted input. In this paper, we argue that adversarial example defense papers have, to date, mostly considered abstract, toy games that do not relate to any specific security concern. Furthermore, defense papers have not yet precisely described all the abilities and limitations of attackers that would be relevant in practical security. Towards this end, we establish a taxonomy of motivations, constraints, and abilities for more plausible adversaries. Finally, we provide a series of recommendations outlining a path forward for future work to more clearly articulate the threat model and perform more meaningful evaluation.

1 Introduction

Machine learning models for classification, regression, and decision making are becoming ubiquitous in everyday systems. These models inform decisions about our health care and our finances, what products we buy, what media we consume, and how our cars drive. On many of these tasks—most notably those related to visual object recognition—deep convolutional networks achieve impressive accuracy and are commercially useful. Nevertheless, these machine learning systems make mistakes and it is important to understand how, when, and why these errors arise.

Of particular recent interest has been the investigation of errors arising from maliciously crafted inputs, or “adversarial examples”. Although there is not a consistent definition in

\textsuperscript{*}Equal Contribution
the literature of what makes an input an adversarial example, we will adopt the definition
from Goodfellow et al. [1]: “adversarial examples are inputs to machine learning models
that an attacker has intentionally designed to cause the model to make a mistake.” This
definition makes it clear that what is important about an adversarial example is that an
adversary supplied it, not that the example itself is somehow special. The definition we
adopt is broader than the definition stated in, or implied by, much of the recent literature.
Recent work has frequently taken an adversarial example to be a restricted (often small)
perturbation of a correctly-handled example. A seed of this focus on small perturbations
was the potentially surprising errors in neural network models for computer vision described
in Szegedy et al. [2]. In particular, Szegedy et al. [2] showed that one can start with an
image that is correctly classified by a state-of-the-art visual object recognition classifier
and then make a small perturbation in pixel space to the image to produce a new image
that the classifier labels differently. To a human, the perturbed image typically appears
indistinguishable from the original, highlighting the limitations of the analogy between
human perception and the processing done by machine learning systems.

While there are many machine-learning-centric reasons to understand the phenomenon
studied in Szegedy et al. [2], a great deal of recent work on adversarial examples has focused
specifically on security. There is a torrent of work [3–72] that views increased robustness
to restricted perturbations as making these models more secure. While not all of this work
requires completely indistinguishable modifications, many of the papers [6–15] focus on
specifically on small modifications, and the language in many suggests or implies that the
degree of perceptibility of the perturbations is an important aspect of their security risk (e.g.,
“by slightly altering the car’s body” [7]; “while being quasi-imperceptible to a human” [8])
while others have argued that defenses against small or local perturbations (imperceptible
or perceptible) improve security.

In this work, we refer to papers that study defenses against unrealistically-restricted
perturbations of correctly handled input examples as the “perturbation defense” literature.
Our focus is on perturbation defense papers that are motivated by security concerns and seek
to reduce the errors of machine learning systems arising from the worst-case perturbation
of a correctly-handled input, within a restricted set. We are not concerned with the much
broader literature that frames learning and estimation problems as minimax games, or with
studies of perturbation defenses that are motivated by, e.g., generalization performance or
biological mimicry, rather than security.

Our goal is to take the idea of an adversarial example as a security threat seriously and
examine the relevance and realism of the particular subset of adversarial examples considered
in the perturbation defense literature. To understand how this literature relates to security,
we introduce a taxonomy of rules governing games between an attacker and defender in
the context of a machine learning system. These rules are motivated by real-world security
scenarios. On the other hand, we underscore that the rules of the game addressed by the
perturbation defense literature do not capture real life security concerns.

Researchers studying adversarial examples should be more explicit about the specific
motivations for their research. In this work, we reserve the bulk of our attention for the
motivations and metrics of security-based adversarial example research. However, Section 5
describes non-security reasons to study adversarial examples and some appropriate metrics
to use for these non-security topics.

\footnote{In more recent work, the perturbations are usually large enough to be perceptible [3–5].}
1.1 Related Work

The broader field of machine learning security has a long history and our critique does not apply to some existing work, for example, on spam detection [73] (this uses an $l_0$-constrained attack model but provides a realistic justification for it), malware detection [74], and securing network intrusion detection systems [75, 76]. As described in the review by Biggio and Roli [77], the perturbation defense literature has, for the most part, developed without close connections to this prior work, although both consider learning strategies in the presence of adversarially constructed inputs at test time.

Prior work on machine learning security has introduced taxonomies for more general machine learning setups and the taxonomy we introduce in this work can be viewed as extending the “exploratory attack” framework presented in Barreno et al. [78]. Recall that in our definition, adversarial examples are examples constructed by an adversary, intended to cause harm. The taxonomy defined in Barreno et al. [78] considers a generalization that measures the amount of harm, assuming that the attacker and defender each have a cost function that assigns a cost to each labeling for any given instance. Our choice to consider a binary definition is for simplicity, and more general cost functions could be interesting depending on the specific system being considered.

2 Possible Rules of the Game

The notion of an adversarial example arises from an abstract two-player game between an attacker and a defender where the defender is trying to solve a prediction problem with a model that has been learned from data. The rules of these games provide a firm ground for what is meant by “adversarial example”, a phrase which requires a clear concept of an adversary. Games intended to inform computer security must capture the essential properties of a realistic threat model. The most interesting threat models will be well defined, clearly stated, and have attacker goals inspired by real systems. Moreover, useful threat models will also be non-trivial in the sense that no attack or defense should exist that is always successful and practical. The attacker should have meaningful restrictions on their capabilities, but they should also still have the potential to do damage relative to those restrictions. In this section, we develop abstractions and nomenclature that capture different sets of assumptions about the attacker. The taxonomy we introduce expands upon the ones introduced in Papernot et al. [6] and Barreno et al. [78] and is intended to model real-world security settings. Examples of such settings as they fit into this taxonomy are given in Section 3.

What are the goals of the attacker? We assume that the goal of the attacker is to produce a desired behavior for some machine learning system and that success for the attacker is synonymous with inducing a labeling error. If, for some reason, there is an easier way for the attacker to achieve their goal that does not require a labeling error for a particular system of interest then it would be a sign that adversarial example games might not capture something important about machine learning security for that system (see Section 4, Figure 3 for an example of such a case). However, there is a significant distinction between situations where the objective is to induce the system to produce a specific error versus those where any error suffices. Following Papernot et al. [6], we refer to the former as a targeted attack, where the adversary only succeeds if, e.g., a cat image is labeled as a dog, and the latter as an untargeted attack where the adversary succeeds if the cat image is labeled as anything other than a cat.
What knowledge does the attacker have about the machine learning system? As defined in Papernot et al. [6], there are different levels of knowledge that one might assume the attacker has about the system. At one extreme, we might assume that an attacker has full knowledge of the model internals and training data, i.e., the whitebox setting. Alternatively, one might assume that the system details are unknown—the blackbox setting—but that the attacker may interrogate it by asking it to label inputs. A further restriction of the blackbox setting would limit the number of such queries the attacker may make to the system [6].

What is the action space of the attacker? A fundamental component of any security analysis is an explicit and realistic consideration of the options available to the attacker. A key assumption of much (but not all, as discussed in Section 5) of the perturbation defense literature is that the imperceptibility of the modification is important to the attack and so the adversary has a tightly constrained action space. Although we defer an in-depth discussion of the standard rules used in the perturbation defense literature to Section 4, many works take for granted that the attacker is required to be stealthy in their perturbations; norm-based proxies for perception are thus frequently treated as constraints on the attacker. A closely related question is what constraints are placed on the attacker’s “starting point”? That is, a discussion of perturbation requires an object to be perturbed; where did this initial example come from? Does the attacker get to choose it, or is it sampled from the data distribution? These two aspects of the attacker’s action space lead us to identify several salient situations for consideration:

• **Indistinguishable perturbation:** The attacker does not get to choose the starting point, but is handed a draw from the data distribution. Any changes to this example must be completely undetectable by a human. We prefer the term indistinguishable here because it emphasizes the comparison with the starting point. This generalizes to a probability of distinguishability; some attacks may benefit from being “less distinguishable” while not relying on 100% indistinguishability.

• **Content-preserving perturbation:** The attacker does not get to choose the starting point, but is handed a draw from the data distribution. However, the attacker may make any perturbation to the example they want, as long as the content is preserved. That is, if it is a picture of a particular person, it must clearly still be that person.

• **Non-suspicious input:** The attacker can produce any input example they wish, as long as it would appear to a human to be a real input.

• **Content-constrained input:** The attacker can produce any input example they wish, as long as it contains some content payload, e.g., it must be a picture of a cat, although it is not constrained to be a particular cat (as in the content-preserving case). This category also includes payload-constrained input, where human perception may not play a role but, e.g., a piece of malware must preserve its intended function.

• **Unconstrained input:** The attacker can produce any input they want in order to induce desired behavior from the machine learning system.

---

2This distinction has also been made in earlier work on spam detection. For example, Barreno et al. [78] differentiate between a spammer who wishes to get any content through a spam filter vs a particular message through the filter.
Somewhat orthogonal (and generally application specific) constraints on the attacker can arise from their tools or their need to realize their attack in the physical world. We distinguish between constraints based on physical modifications of objects and constraints based on the interaction with the defender or a third party human observer. For example, assume an attacker can apply sufficient makeup or prosthetics to their face to impersonate a given person. Even though in some sense they start with their undisguised face, the notion of a starting point would only really make sense if the defender got to see their face before any disguise gets applied. A reasonable set of game rules for a physical disguise scenario might formalize the action space as any non-suspicious input since the attacker can put on a mask to make their face look like any person, not just themselves, as long as the defender cannot detect that they are wearing a mask. A key question for the purposes of this taxonomy is whether or not there is security relevance for human perceptual distance between the starting point and the attacker-supplied example.

Who goes first and is the game repeated? Closely related to the whitebox/blackbox dimension are questions around the game sequence. Does the adversary first produce a data distribution and then the defender builds a model? Or does the defender only build one model that needs to be robust to all potential adversarial data distributions? The game could be repeated or played in real time where computational concerns become relevant. However, the defender is at a significant advantage if the attacker goes first. In particular, any procedure defined by an adversary which does not depend on the defender’s model ultimately defines a distribution over inputs. A defender could use samples collected from this distribution to help train a new model with better performance against this particular procedure. The current perturbation defense literature generally considers the setting where the defender goes first and needs to be robust to all potential attack distributions. Whatever method the adversary uses to build adversarial examples ultimately defines some distribution of inputs, which could be easily detected statistically as in Hendrycks and Gimpel [41], Grosse et al. [64], and Feinman et al. [69] so long as the attacker must go first. Of course if the method for generating an adversarial example depends on the parameters of the defender’s model(s), then there is no well-defined static distribution for the defender to detect. This back and forth already happened in the defense literature when Carlini and Wagner [79] “broke” many existing detection methods. More clarity on the rules each paper considers might have avoided this cycle of falsification. For further discussion on this axis we refer the reader to Biggio, Fumera, and Roli [80] which defines the notion of reactive (defender can adapt to current attacks) and proactive (defender must anticipate the attack) defense strategies.

2.1 Relevance of Machine Learning

Unlike other subproblems in machine learning security, such as training set poisoning, defending against adversarial examples is not specific to learned functions. It may also be possible to fool a hand-crafted, non-statistical classification algorithm with adversarially constructed input examples. Human defenders who make classification decisions directly are by no means infallible and can also be deceived by data supplied by an adversary. For example, our visual faculties can be deceived by camouflage and disguises, not to mention adversarial lighting conditions, smoke, or mirrors. Time-limited humans may also be fooled by perturbation-based adversarial examples [81]. The notion of an adversarial example is not specific to neural networks or to machine learning models. Adversarial robustness is an instance of the much broader phenomenon sometimes called Goodhart’s Law [82], where a
metric ceases to be useful when it is used as a target for optimization. A reason to study adversarial examples in the context of machine learning is because functions produced by machine learning algorithms actually get used in important applications and such functions may have counterintuitive or poorly described failure modes that do not follow historical patterns of human, or even software, failures. Nor will these failure modes necessarily be obvious from measuring error on held out data from the training distribution.

3 Example Attack Scenarios

Our taxonomy from the previous section establishes different axes of variation for the rules of an adversarial example game, but does not give us guidance on what specific rule sets are the most interesting to study from the standpoint of securing real products, services, and systems. A valuable taxonomy will include multiple points that align well with systems that actually exist and that plausibly have motivated attackers, so in this section we describe several scenarios that we find compelling. That said, we do not expect every point in our space of possible rules to correspond to a realistic example, nor do we expect our list of examples to exhaustively cover important security situations where adversarial examples are relevant. Instead, our contention is that if one wants to study a particular set of rules in a security context, then one must provide at least one sufficiently motivating example for that ruleset. Furthermore, although we should be forward looking in our research and proactively consider hypothetical future threats, we should have a bias towards situations which are motivated by real-world scenarios. These examples can also help us discuss different rule sets by providing terminology, help us understand different classes of constraints and objectives, and help us identify games that have already been studied in other contexts.

Although we intend for these examples to be illuminating, they should be treated as sketches that do not reflect a complete understanding of the specific threat. We do not claim to completely understand all the relevant facts about the particular systems we mention. In actuality, our examples are only a first, cursory step of a much more involved analysis. However, we believe that making an honest attempt at this sort of analysis, even in the form of a rough outline, is the bare minimum necessary to motivate our research from a security perspective.

3.1 Attacks with Content Preservation Constraints

Consider an attacker with the goal of illegally streaming copyrighted content, e.g., a pay-per-view boxing match, to an audience who has not paid the subscription fee. The attacker needs to evade an automated system that uses a statistical model to decide if the attacker’s stream matches the copyrighted stream. The attacker can try to perturb the content to evade detection by the machine learning system that might shut down the stream. This attack is untargeted and requires a content-preserving perturbation or the stream viewers will not be able to enjoy the boxing match. There is no need to create a video indistinguishable from the original video; viewers are willing to tolerate slightly different cropping (or adding a larger background) or other obvious changes. Note that in this case the adversary is colluding with the human viewers—the viewers will gladly tolerate perceptible perturbations so long as they do not interfere with the enjoyment of the media. Furthermore, these attacks exist in the wild, and they commonly involve applying large and obvious transformations to the video,
such as cropping, re-filming a television screen, or even more creative transformations.

Another variant of this pay-per-view attack is a situation where the bad actor seeks to post specific compromising images on social media while evading machine detection or automated filtering. We refer to this as a revenge porn attack, and like the pay-per-view attack, it is untargeted but places content preservation constraints on the attacker (the attacker-produced image should clearly be of the person they are trying to harass). It is different, however, in that the perceiving human is neither a collaborator nor an adversary, but a neutral third party.

3.2 Non-Suspicious Attacks

We also believe there could be compelling examples where the adversary only has a weak constraint to produce a non-suspicious input. One such example might be a voice assistant attack. In the voice assistant attack, the adversary wishes to manipulate an in-home device such as an Amazon Echo into bad behavior, e.g., unlocking a security system or making an unauthorized purchase, via audio that appears to be innocuous, such as a voicemail or television advertisement. Unfortunately, to make this example interesting, we have to make additional assumptions about the voice assistant design that might not hold in practice. Specifically, we need to assume that the voice assistant does not produce an audio reply to confirm the malicious command and that a human whose suspicions must not be aroused is present and listening during the interaction. If the attacker is not concerned with an automated reply, they arguably would not be concerned with the original audio sounding suspicious either and this scenario might qualify as an unconstrained attack.

The voice assistant attack has been explored in some prior work. For example, Carlini et al. [83] demonstrate hidden voice commands that are unintelligible to human listeners but which are interpreted as commands by devices. This work defined the attack constraint to be any input which is unintelligible to a human third party. Follow up work [84] demonstrated that it is also possible to fool speech to text systems with small perturbations to a clean audio source, where the adversarial audio is 99% similar to the original. These alternatives for an attacker create an interesting question for defining the threat model of a given system: how much less suspicious would a human find a nearly-indistinguishable sample from a clean audio file (e.g., perhaps modified from typical background noise in the environment) than a brief, unintelligible noise? The answer to this question clearly depends on the deployment environment. Perhaps a more general question for future work is, what is the space of non-suspicious audio files? Of course, attackers need not be limited to small perturbations of a randomly chosen (or environmentally-supplied) starting point; they also have the flexibility to construct a “non-suspicious” input from scratch.

Another example of a non-suspicious attack constraint is an attack against facial biometric systems for surveillance and access control. Suppose that a group of attackers all have their faces stored in a database that maintains a blacklist of people who are banned from a certain area and their goal is to get any one of their number inside the restricted area. Furthermore, suppose that automated camera systems watch for faces matching the attackers over the entire area and security guards patrol the area and guard the entrances looking for any suspicious activity. The guards do not know the faces of everyone banned from entering, but they are trained to make sure everyone who enters has their face visible and to watch for suspicious behavior. Here the attackers can produce any disguise starting

3https://qz.com/721615/smart-pirates-are-fooling-youtubes-copyright-bots-by-hiding-movies-in-360-degree-videos/
from any of their number that they want, as long as the result still looks like a real person with a mostly uncovered face. As in the voice assistant attack, when circumventing a face recognition blacklist, the adversaries have weak constraints that are not usefully abstracted as perturbations of a fixed input example, even though they might have some restriction to physically realizable disguises. If there are no guards watching the automated system, this setting would be classified as an unconstrained attack. One could also consider situations where the attacker must impersonate anyone on a whitelist contained in the database in order to be granted entry. This setting has been explored from the attack side in Sharif et al. [85]. However, as discussed in Section 4, there are situations where the best options available to the attacker involve fooling both the computer vision model and any human guards on site.

3.3 Attacks with Content Constraints

Examples of scenarios where attackers have payload constraints are familiar to everyone who uses email, predating the restricted adversarial perturbation defense literature by decades. In the email spam scenario, the objective of the spammer is to produce any input that evades machine detection (untargeted) while satisfying some semantic content or payload constraint, e.g., it delivers an advertisement. Motivated attackers and defenders already exist, as spam filtering has significant commercial value. Also, this example shows the value of considering a repeated game, which significantly changes how a defender may approach the problem. Email spammers may also use image attachments to deliver their payload, and may craft these images in order to evade any automatic detection [77]. For examples of such real-world attacks see Figure 1. Note that these images are crafted from scratch to avoid detection, and they are different than what might result from making a small perturbation to a random image from the data distribution.

Another important example of a payload constrained attack in the wild is modifying malware to evade statistical detection, where the adversary can construct any input that delivers a malicious payload. Malware authors have full control of the input, but need to have working malware. The notion of an action space can be stretched to include all programs that compile and deliver the payload. The attack objective is to produce a binary which causes some targeted behavior on the machine. This game is played in real time on a large scale similar to that of spam detection, although existing malware defense mechanisms do not always use machine learning. Statistical malware classifiers do exist, however, for example neural networks have been applied to this problem in Dahl et al. [86]. Since statistical malware detectors have non-zero test error, they are often deployed under the assumption that a motivated attacker can fool them and under conditions where the attacker has weak economic incentives to try to circumvent them. For instance, a statistical malware detector might target previously known malware families employed by unsophisticated attackers or be used to accelerate analysis of already successful malicious binaries by routing them to the correct experts. As with the spam case, economically motivated attackers already exist. Attacks on malware detectors have been studied in some prior work [87, 90], and a few defenses have been proposed in Kreuk et al. [90] and Grosse et al. [91]. However, as discussed further in Section 4, these defense papers impose more restrictions on the attacker than are actually motivated by this setting.

Also in this category is what we call the content troll attack where the attacker’s goal is simply to get any objectionable content onto a social media service. In this example, attackers are willing to make potentially large and perceptually obvious changes to their
images or videos as long as they maintain the specific semantic content. Interestingly, neither the attacker nor the defender completely control the data distribution, but questions about how the game gets repeated, the definition of visual semantic equivalence, and when humans flag violations become crucial.

Figure 1: An example of image spam shown in Biggio and Roli [77]. Note the notion of a “starting point” does not apply here, instead the entire image is crafted from scratch by the attacker to avoid statistical detection. It is not of the form of applying a small or imperceptible perturbation to random image from the training distribution. Thanks to Battista Biggio for permission to use this image.

These attacks are widespread real-life examples of adversarial interaction with machine learning systems and have received significant academic and industrial attention, and defenses against these attacks make much weaker assumptions about the attacker than are typically made in the adversarial perturbation defense literature.

3.4 Attacks Without Input Constraints

The most general assumption we can make about the attacker action space is that they can produce any input example they want with no restriction to perturb some starting point or deliver some specific content. Some variants of the voice assistant scenario we mention above are best described as using an unconstrained attacker action space. Another example we will call the stolen smartphone scenario is when an attacker wishes to unlock a stolen smart phone that uses face recognition authentication via depth and intensity images of the user’s face. The iPhone X has such a feature and, incidentally, uses neural networks as
part of the authentication algorithm. Although there is a constraint on the attacker given the need to realize the attack in the physical world, as discussed in Section 2, this is an orthogonal consideration to the taxonomy we introduce. Successful adversarial attacks against this system have been demonstrated in prior work.

3.5 Indistinguishable Perturbations

In contrast to the other attack action space cases, at the time of writing, we were unable to find a compelling example that required indistinguishability. Given the ubiquity and commercial importance of machine learning, our goal was to find a real product, service, or system that made sense to attack where the indistinguishable perturbation constraint seemed realistic and captured the essential aspects of the threat. In many examples, the attacker would benefit from an attack being less distinguishable, but indistinguishability was not a hard constraint. For example, the attacker may have better deniability, or be able to use the attack for a longer period of time before it is detected. However, this flexibility on the attacker’s part is important: if they cannot attack with an indistinguishable perturbation, they may still succeed with a less-constrained perturbation, or by choosing a different starting point.

Regardless of whether a scenario that requires an indistinguishable perturbation later emerges, several of the scenarios above that have different constraints are useful to study from a security standpoint; in fact, some of them have been studied for many years. We believe, therefore, that it is important for security-motivated work within the machine learning community to expand its focus to include a broader set of rules for attackers and adversarial inputs.

4 Standard Rules in the Perturbation Defense Literature

Having outlined different rulesets for potential adversarial games and described some motivating examples of specific rulesets, we can try to place the recent adversarial perturbation defense literature within our taxonomy. In some respects, the perturbation defense literature is remarkably consistent in the game rules considered. Although many papers do not clearly state the rules of the game nor include consistent definitions of the term adversarial example, we can infer from evaluation protocols and informal descriptions a common set of standard rules that apply to well over fifty recent papers, and perhaps many more. Nearly every perturbation defense paper we surveyed assumes the attacker receives a starting point that is a draw from the data distribution; the adversary is allowed to apply a perturbation to this starting point with $l_p$ norm up to some given $\epsilon$, with the goal of inducing a specific or nonspecific error. As mentioned in Section 2, many examples in detection methods or black-box defenses are unclear on whether the defender must produce a proactive or reactive defense. Carlini and Wagner pointed out that several attack detection methods do not provide proactive defenses, but did not discuss whether they would have any merit as reactive defenses. For the sake of argument, we take the standard rules to require a proactive defense since this position seems more common.

In practice, many papers consider a particular gradient-based attacker strategy within these rules in which the attacker searches for an approximate solution to the following

---

4 https://www.wired.com/story/hackers-say-broke-face-id-security/
optimization problem:

$$\delta_{adv} = \arg \max \frac{\delta}{p} \sum_{y} L(x + \delta, y)$$ \hfill (1)

The standard, and sometimes only, evaluation metric used in the perturbation defense literature is the following quantity, often referred to as “adversarial robustness” \[93\]

$$\mathbb{E}_{(x,y) \sim p(x,y)}[1(f(x + \delta_{adv}) \neq y)]$$ \hfill (2)

Here \(\delta_{adv}\) is the approximate worst case perturbation found in equation (1), \(f(x)\) is the model’s prediction on sample \(x\), and \(y\) is the true label associated with the starting point. In principle, for an optimal perturbation, adversarial robustness would measure the probability that a random sample from the data distribution is within distance \(\epsilon\) of a misclassified sample; this robustness notion is an expectation over the data distribution, not a worst case guarantee. Variants of this metric have been defined explicitly in Madry et al. \[4\] and Cisse et al. \[63\], however most papers simply report accuracies against small, adversarially constructed perturbations where they vary the method used to generate the perturbation.

Using a specific approximate optimization algorithm to find \(\delta_{adv}\) turns reported robustness scores into potentially loose bounds (in the wrong direction). Difficulties in measuring robustness in the standard \(l_p\) perturbation rules have led to numerous cycles of falsification \[79, 94, 95\]. This difficulty in evaluation has affected a substantial subset of the defense literature. The efforts of Carlini and Wagner \[79\], Athalye, Carlini, and Wagner \[94\], and Carlini and Wagner \[95\] have shown that a combined 18 prior defense proposals are not as robust as originally reported. A number of other papers exhibit worrying examples of what we refer to as hardness inversion. Hardness inversion is when the reported robustness is higher for a strictly more powerful attacker. In general, we would expect defense methods to become less effective as the adversary has fewer limitations, since a more powerful adversary can always mimic a weaker one. One example of hardness inversion is when a paper reports higher robustness to whitebox attacks than blackbox attacks. Another example would be reporting higher accuracy against an untargeted attacker than a targeted attacker (e.g. Song et al. \[50\]). Hardness inversion is a sign of an incomplete evaluation, such as an attack algorithm getting stuck in a local optimum. Several indicators of hardness inversion were identified in Athalye, Carlini, and Wagner \[94\]. Heuristics such as hardness inversion provide a sanity check for evaluations in the standard rules, but they might not be enough since we do not expect these evaluation difficulties to have a simple resolution; computing \(l_p\) perturbation robustness in the standard rules is NP-hard in general \[96\]. The primacy of this single metric within the adversarial perturbation defense literature is disquieting given how frequently later work falsifies reported values of the metric.

Our goal here is to understand the perturbation defense literature in the context of security, but unfortunately the action space of the standard rules does not fit perfectly into the taxonomy introduced in Section 2. This lack of fit, in our view, is not because of holes in the taxonomy but because of weak motivation for this action space. The closest conceptual fit for this ruleset within our scheme is the indistinguishable perturbation ruleset. It is certainly true that sufficiently small \(l_p\) perturbations will produce examples that are indistinguishable from the original. However, if the objective is to achieve indistinguishability from a starting point, \(l_p\) is known to be a poor proxy for measuring what humans actually see \[97\]. That is, if we take seriously the spirit of the rules articulated by much of the perturbation defense literature—randomly chosen datum as starting point and an imperceptible perturbation—regardless of whether it is a realistic attack it is nevertheless clear that many difficult to perceive perturbations are available to an attacker that could...
have large $l_p$ norm. Increasing $\epsilon$ does not provide a solution, as the locus of images exactly $\epsilon$ away from a starting image will include obviously perceptually different images as well as images that take a long time to detect as different (see figure 2). As a further motivating example, a 1 pixel translation of an image would be a subtle modification to humans, but for most images would be a large perturbation in any $l_p$ metric. Moreover, any notion of indistinguishability from an original image depends on psychometric factors such as how much time the observer has to make a decision, and whether or not they are motivated to discover differences. These kinds of considerations make the standard perturbation ruleset difficult to connect with realistic adversarial action spaces.

### Figure 2: Images equally far away from a reference image in the $l_2$ sense can be dramatically different in perceived distance. Figure due to Wang and Bovik [97].

#### 4.1 Common Motivating Scenarios for the Standard Rules

Although there may be good reasons to study the standard rules that have nothing to do with security, if we are interested in doing work on adversarial examples that improves security in important applications, we should study the most plausible and practical ruleset we can. We should think carefully about how well the game rules we study capture relevant features of realistic threats. Unfortunately, the security-motivated adversarial perturbation defense literature only occasionally mentions real-world examples to motivate their work and almost never discusses them at length. We are also not aware of any applied work
using the standard rules that tries to secure a real system and performs threat modeling. Below we examine several examples that have been used in the literature as motivation, and examine how realistic they are. One part of our examination is to ask basic questions about whether the standard rules fit these motivating scenarios, but we also consider a higher level question: \textit{if a motivated adversary had the stated goal, how likely is it that they would prefer the adversarial perturbation framework as their means of attack over other attacks that have no technical machine learning component?}

4.1.1 The Stop Sign Attack

Perhaps the most common motivating scenario (e.g., in Evtimov et al. [40] and Lu et al. [98]) is the “adversarial street sign” in which an attacker can only make tiny modifications to a street sign, with the objective of fooling self driving cars. Suppose the goal of the attacker is to make self driving cars crash by altering a street intersection containing a stop sign in some way. In the worst case, the attacker can choose any naturally occurring stop sign as the starting point, but we can also consider an attacker with the goal of targeting a specific intersection. Imperceptible perturbations are not strictly required; while in some cases, subtlety will strengthen the attack, in general, the attacker can make essentially any modification to the sign or the surrounding area. Stickers, scratches, or any kind of defacement could be used, leading to arbitrarily large and fully-perceptible perturbations of the sign. The physical world adversarial stop signs in Evtimov et al. [40] are far from subtle and ignore the standard rules unless we argue that they use “small” perturbations in the $l_0$ metric. Even if we view Evtimov et al. [40] as using the standard rules with a relatively large $\epsilon$ and the $l_0$ metric, their attack still takes a lot of effort and expertise compared to just covering a larger area of the sign with a picture of another sign, placing a bag over the sign, or knocking it over (Figure 3).

Taking a broader view, self driving cars must also handle naturally occurring situations such as stop signs that blow over in the wind, intersections that should have stop signs but for whatever reason don’t, and pedestrians wearing shirts with road signs printed on them.

State of the art stop sign detection accuracy is not 100%, therefore some positive fraction of naturally occurring stop signs will be misclassified by machine learning systems. Designers of self driving cars will already have to build control systems that can safely handle errors in stop sign detection. Even if test accuracy for automated stop sign detection reaches 100%, self-driving cars must still safely handle the case where stop signs are missing entirely. A stop sign classifier that performs worse on the real-world distribution of unaltered stop signs but has increased robustness to small imperceptible adversarial perturbations does not seem obviously desirable.

State of the art object detection is known to be extremely brittle. For example, Rosenfeld [100] showed that randomly moving around an object in the background may occasionally cause other objects to go undetected or become misclassified. It would be prudent for some future work to consider improving robustness to these sorts of naturally-occurring transformations as well.

4.1.2 Evading Malware Detection

Another security setting commonly cited in the perturbation defense literature is evading statistical malware detection. In fact, there are at least two perturbation defense papers

---

5A cursory web search for “speed limit street sign t-shirt” reveals many vendors of such shirts.
which specifically consider defense strategies for increasing neural network robustness to restricted $l_0$ changes to a feature vector constructed from a malware binary \[91, 101\]. We have already discussed this application as it fits into the payload constraint action space (the resulting binary must still function and achieve the goal of the attacker). This is certainly a setting where security is a concern and where real attackers exist, but it is not a good match for the standard rules. We find it implausible that malware authors would restrict themselves to modifications of a randomly sampled malicious binary from the training distribution, let alone modifications that are small in an $l_0$ sense in the defender’s feature space. Malware authors only consider the features the defender will extract from their malware when it helps them achieve their goals. There is a vast action space of code alterations that preserve essential functionality. Sophisticated malware authors already produce polymorphic viruses with encrypted payloads and randomized decryption routines. Imperfect malware classifiers
might still be useful in some cases; for example, if they operate on features that are costly for the attacker to alter, faulty classifiers may still be useful under appropriate economic circumstances.

4.1.3 Fooling Facial Recognition

Another example mentioned in the perturbation defense literature is fooling facial recognition. As discussed in the previous sections, we find some versions of this example compelling, but out variation involves only weak attacker action space constraints that do not match the standard rules well. The particular scenario in Sharif et al. [85] cited in the perturbation defense literature differs from our scenario in a small but important way. Unlike the blacklist scenario we consider, they consider a whitelist checkpoint scenario where an attacker must impersonate a specific person to enter a restricted area. We believe that in such a situation, the best option available to the attacker would involve fooling both the computer vision model and any human guards on site. Given the choice, an attacker would prefer a high quality prosthetic disguise that also fooled the human guard to a pair of glasses that just fooled the face recognition system [85]. In fact, given that face recognition systems are not perfect, the guard might be instructed to compare the matching image returned by the face recognition system to the person trying to enter. If, for whatever reason, the guard does not bother to compare the match to the attacker’s face, then this scenario again falls into the non-suspicious case which does not match the standard rules well.

4.1.4 License Plate Camera

Mikhailov and Trusov [102] suggested the possibility that malicious attackers could create an adversarial licence plate to avoid getting traffic camera tickets. In this setting there could be an incentive for the attacker to maintain visual similarity with their original licence plate should they ever be pulled over by the police for unrelated reasons. Although traffic camera image and video capture is automated with induction loop triggers, it is possible for humans to review the photos and for anyone mistakenly ticketed to challenge the ticket in court; triggering a plate reading error would accomplish nothing other than guaranteeing human review. Therefore, an attacker would prefer simpler techniques for evading cameras that would work even on traffic cameras that use human workers to review footage. For example, attackers could use clear sprays that are intended to overexpose (and render unrecognizable) any photographed image of the licence plate. Creative and motivated attackers might find many other means to obscure their plates such as a retractable plate cover, simulated mud, or other minimally suspicious occlusion.

4.1.5 Check Fraud

Papernot et al. [7] suggested the possibility that an attacker could create an adversarial check to force a neural network classifier to read a larger amount than what is written. Check fraud already exists in the wild and does not rely on fooling any machine learning system. Furthermore, transactions will only be reversed more quickly if the image the ATM captures of the check does not match the transaction when examined by a bank teller, making traditional forgery potentially more appealing.

4.2 The Test Set Attack

One useful litmus test for games being studied by the perturbation defense literature is to ask whether an adversary could usefully execute a test set attack. The test set attack is simplistic and it makes no perturbation at all, rather the adversary blithely hopes the random starting point from the data distribution will be misclassified. Unless we add new rules to the game to prohibit it, all defenses we have surveyed are vulnerable to the test set attack given that they report a non-zero error rate on the test set. Because many perturbation defense papers we reviewed apply defenses that increase error on the test set [4, 7, 9, 14, 20, 23, 36, 42, 45, 103, 104], these methods are actually more vulnerable to the test set attack than an undefended model. Additionally, since most of these papers consider perturbations with support on the entire image and assume that attackers have access to the train and test data, it would be natural to assume that attackers could also employ more powerful attacks that ignore the search radius entirely [105], or simply feed in samples from the test set until an error is observed. Test error is the best unbiased estimate for the error rate of the model in the data distribution that the test set was sampled from, so papers that claim \( l_p \) adversarial robustness that increase test error have at the same time verified that their proposed defense causes more errors to occur in this distribution.

Because some defenses may improve robustness under certain attack models, while reducing robustness under others, future defense papers should explicitly state their assumptions about the distribution of inputs the system will be subject to, and the weights attached to erroneous handling of those inputs. They should further indicate, and evaluate, whether they are designed to be robust to attacks from other distributions, such as the test set attack. Practical systems that expect to face attackers that perform simplistic limited query attacks who are not constrained to imperceptible perturbations, for example, would likely avoid defense mechanisms that improve \( l_p \) robustness at the expense of a worse error rate under the expected real-world distribution. Beyond being clear about the link to the threat model, the security context may also change the weight attached to incorrect examples: misclassifying an important email as spam is more costly than classifying a spam email as benign. Indeed, designers of spam classifiers already take this into account when designing the objective function. Ultimately, in the face of uncertainty about attacker goals, capabilities and constraints, a classifier that makes mistakes in a larger volume of the input space intuitively should only be easier to attack, and that input space is defined by the restrictions placed upon the attacker for generating input examples.

In some cases, small but non-zero test error may even logically imply that the model is sensitive to small perturbations to randomly sampled inputs from the data distribution. Gilmer et al. [106] proved such a result for a specific high dimensional dataset. They also showed that neural networks trained on this dataset demonstrate close to optimal \( l_2 \) robustness given the amount of test error observed. This result potentially has implications for the perturbation defense literature as it shows that the only way for a defense algorithm to increase robustness in the \( l_2 \) metric is to significantly reduce test error, which is something that most defenses we reviewed fail to do for image datasets. This work also demonstrated how difficult it can be to secure a model against a powerful adversary. In fact, they showed that an adversary can reliably find errors even when the test error rate of the model was less than \( 10^{-8} \). This tight bound on \( l_2 \) robustness in terms of test error rate has not been shown to hold for image datasets, but it may also be moot if \( l_2 \) robustness has minimal security relevance anyway.

---

8 In Section 4.2.1 author Ian Goodfellow presents an alternative to this formulation.
The results on this synthetic dataset underscore an important principle: for many problem settings, the existence of non-zero test error implies the existence of adversarial examples for sufficiently powerful attacker models. Of course test error can also be measured with respect to noisy distributions such as Gaussian noise or random translations and rotations. In fact, applying random perturbations to an image has been shown to be an effective way to find errors. As we discuss further in Section 5.2 reducing test error with respect to various classes of noisy image distributions that exceed the threshold of typical imperceptible modifications is well motivated and a necessary step towards securing a model against attackers constrained to content-preserving perturbations. Generalization to noisy image distributions has, of course, been studied in the past. In fact, Globerson and Roweis developed techniques for improving generalization when pixels may be randomly deleted. In addition to studying the random noise case, Globerson and Roweis also gives theoretical worst case guarantees.

If we consider more realistic rulesets than the standard rules where attackers have full control over the input to a classifier, then finding model errors with only limited query access and no knowledge or expertise in machine learning can still be quite easy. As an illustrative example we collected instances of real-world attackers fooling the “Not Hotdog” application, a popular smartphone app that classifies images as containing a hot dog or not. It is reasonably accurate on naturally occurring images. Even though the “Not Hotdog” app is of little commercial importance, it is an interesting example where attackers ignore the notion of imperceptibility and use physical world attacks to fool the model in a black box setting without needing knowledge of the model architecture or training data. Despite presumably having no special expertise in ML, these attackers are quite successful. See Figure 4 for several examples of these attacks. We collected these examples by searching for tweets containing #NotHotDog on Twitter. Our point with this example is that we can view the attackers as implementing the test set attack, at least for the minimally staged, completely benign real images (the granola bar or traffic cone). Some of the more humorous images could be unlikely under the training distribution (such as the dachshund in the hotdog costume), but are qualitatively similar to other generalization errors. We could imagine finding these images with hard-negative mining from a large set of images from the web.

4.2.1 An Alternative View of Test Design and Error in Adversarial Conditions

Author Ian Goodfellow suggests a different view than what is presented in the previous subsection: the IID test set included in most academic benchmarks is not necessarily reflective of the actual conditions under which a model will be deployed. Researchers studying different topics should attempt to approximate actual deployment conditions more realistically. In most cases, the volume of errors is not relevant. For traditional supervised learning, the frequency of encountering errors on an IID test set is what matters most. For security, there are many other considerations, such as whether the errors are easy to find, shared between many models enabling black box transfer, highly repeatable, etc. For example, the FGSM attack defines a volume of measure zero that contains an error with very high probability for most undefended models, and it is straightforward for an attacker to exploit this kind of error due to its predictability even though the volume of these errors is zero. When determining how to trade accuracy on an IID test set versus accuracy facing an adversary, the tradeoff should be made by attempting to approximate the actual deployment conditions.
as best as possible. In most cases it is probably unrealistically optimistic to assume that an attacker is never present (optimize for IID test error) and unrealistically pessimistic to assume that an attacker is always present (optimize for error on adversarial examples). The evaluation in Kannan, Kurakin, and Goodfellow [5] shows one way to select an appropriate model for a variety of possible test sets (Figure 5).

4.3 Security and the Standard Rules

To summarize:

- Commonly-used motivating examples for the standard rules are typically unrealistic threat models.
- When the motivating examples involve more realistic threats, the standard ruleset does not usually apply.
- We have not found real-world examples for the indistinguishable perturbation setting, so even if small $t_p$ perturbation norm constraints from the standard rules were a perfect approximation for human perception, the standard perturbation defense rules currently lack a strong security motivation.
- When the starting point is a randomly chosen datum, “adversarial attacks” can be performed without perturbation by simply taking advantage of imperfect out-of-sample generalization.
- Degrading test error should be assumed to make a system less secure.
- Without certainty about attacker constraints and capabilities increasing robustness has no clear relationship to security.
Figure 5: Researchers should attempt to approximate important properties of the actual distribution encountered at deployment of a model. One of these properties is the presence of an adversary. This plot shows how three different models navigate the tradeoff between performance with no adversary (the IID setting) and performance when facing an adversary within a particular threat model (this plot uses a max-norm constrained perturbation threat model with a 10-step attack algorithm, but the same plot could be made for many threat models, including the test set attack). These graphs help to justify specific tradeoffs between IID error and error under adversarial attack. For example, we see here that to justify using the ALP model rather than an undefended baseline, we would need to believe that attackers will use the specified threat model and will be present at least 7.1% of the time. We also see that the M-PGD model is never preferred, though it has both higher IID accuracy than ALP and higher adversarial robustness than the undefended baseline. Figure reproduced from Kannan, Kurakin, and Goodfellow [5].

Of course, it is possible that realistic scenarios may emerge in which the standard rules apply, but even in this case we believe that a diversity of rulesets should be studied, with an emphasis on rulesets widely applicable to high value applications. If a realistic motivating example emerges for $l_p$ robustness, then we would encourage a pragmatic approach grounded in empirical results for that scenario, rather than a broad study of hypothetical corner cases. In the subsequent section, we propose some forward-looking recommendations for research in this area.

5 Moving Forward

The goals of a piece of scientific work determine how that work should be conducted. Much of the perturbation defense literature is motivated by security concerns, asserting that small, error-inducing perturbations of correctly handled examples are a “major security concern in real-world applications of DNNs” [51], “pose a great security danger to the deployment of commercial machine learning systems” [15], and so on. Many papers in the recent perturbation defense literature mention the potential imperceptibility of these perturbations as a specific security vulnerability. Based upon the lack of concrete security scenarios that require the standard game rules, however, we encourage future work to adopt one of two paths: either adopt a broader view of the types of adversarial examples that can be provided
by an attacker, in a way that is consistent with a realistic threat model, or present a more specific rationale (likely not a security motivation) for the use of the standard game rules or the study of small adversarial perturbations.Indeed, much of the adversarial perturbation research arose based upon observations that even small perturbations can cause significant mistakes in deep learning models, with no security motivation attached. Many follow-up works on adversarial examples were not motivated by security and thus did not evaluate their methods with any robustness metric. One follow-up work established a specific metric, the error rate within a specific norm ball, as an intuitive metric to express the notion that changes smaller than some specific norm should never change the class of an example. This use of the norm ball provides a label propagation mechanism, where input points can be confidently assigned labels based upon their proximity to other points that have been labeled. This creates a method of evaluating a model on out-of-sample points, albeit those constrained to a small fraction of $\mathbb{R}^n$. It is difficult to evaluate the rest of $\mathbb{R}^n$ in an automated way.

Goodfellow, Shlens, and Szegedy intended $l_p$ adversarial examples to be a toy problem where evaluation would be easy, with the hope that the solution to this toy problem would generalize to other problems. In practice, the best solutions to the $l_p$ problem are essentially to optimize the metric directly and these solutions seem not to generalize to other threat models. Because solutions to this metric have not generalized to other settings, it is important to now find other, better more realistic ways of evaluating classifiers in the adversarial setting. The number of papers written using the $l_p$ metric shows how quantifiable “rules of the game” facilitate follow-up research, but also indicates the need for carefully defining where those rules are and are not applicable. The history of defenses against norm-ball modifications also demonstrate, unfortunately, that when the primary evaluation metric for comparing defense methods with each other is an NP-hard problem, cycles of falsification may result; we return to these notions in Section 5.2.

5.1 Recommendations for Security Related Work on Adversarial Examples

There is a long history of prior work on machine learning security. Some of this prior work looks at a wide variety of realistic ways that machine learning systems might be attacked, including adversarially constructed inputs at test time. In our opinion, the best papers on defending against adversarial examples carefully articulate and motivate a realistic attack model, ideally inspired by actual attacks against a real system. For example, Sculley, Wachman, and Brodley identified a common real-world attack strategy against email spam detectors where the attacker evades spam detection by intentionally misspelling words typically associated with spam. Sculley, Wachman, and Brodley also designed a classification system robust to such attacks. This spam detector would of course still make errors in the worst case and years later there is still no perfect spam classifier. However, the work made practical sense given the prevalence of this particular attack at the time. It would have made much less sense if there was no connection to real email systems and current or realistic attacker behavior.

Future papers that study adversarial examples from a security perspective, but within the machine learning community, must take extra care to build on prior work on ML security.
particularly when describing a realistic action space for the attacker and in motivating this action space by real systems and attacks that exist in the wild. For security motivated papers it is important to define what an adversarial example is and motivate this definition by at least one real system (it would be even better if the work actually secured a real system). In motivating from a real system, care should be taken as to what assumptions are being made on the starting point of the attacker. For example, in designing a defense for the content troll attack, any illicit image is a potential starting point and the defense proposal should be evaluated with this in mind. In evaluating the defense, if test error degradation is observed then an argument needs to be made as to why this is tolerable for the desired security application. Care should also be taken to avoid instances of hardness inversion, where the defense appears more robust to a strictly stronger attacker. Any instance of hardness inversion is evidence of an incomplete evaluation. We also encourage future work to develop other real-world motivated rule sets beyond the ones introduced in Section 2.

5.1.1 Evaluating a State of the Art Defense in the Content Preservation Setting

The current state-of-the-art defense for the standard rules on the MNIST dataset is due to Madry et al. [4]. This defense has yet to be broken within the $\ell_\infty$ rules on this dataset despite many attempts by other researchers [119]. Suppose instead that the defense was designed to defeat the revenge porn attack, where the attacker wishes to upload embarrassing pictures of a particular person to social media and wishes to bypass a machine learning detector for prohibited content. The attacker in this case must preserve the semantic content of the image, as any produced image must clearly still depict the target person in order to meet the attacker’s goals. As a proxy for this constraint on the MNIST dataset, we could require that any attacker-produced image must clearly be of the original digit. One can ask if this defense is robust in the content preservation ruleset, the most restrictive attacker action space in our taxonomy that still seemed easy to motivate for security applications. We already should strongly suspect that the answer is no, the defense was only designed to be robust to perturbations of size $\epsilon$ in the $\ell_\infty$ metric and Sharma and Chen [115] has already shown that the defense is not robust to small perturbations in other metrics. Nevertheless, as an exercise, we can try a simple attack designed to satisfy the content preservation constraint and intentionally ignore any notion of indistinguishability or “smallness” of the perturbation. In order to preserve the content of the image, our attack arbitrarily modifies the unimportant pixels in the background of the image. For the special case of MNIST, we define the background as the complement of the foreground, where the foreground is all pixels within distance 2 (in the Manhattan metric) of a pixel with value larger than .7. Although this heuristic is tailored specifically for MNIST, in more general attack settings we could imagine a motivated attacker defining an image-specific background mask by hand. Figure 6 shows the results of this attack and (unsurprisingly) the defense is 0% robust to this attack. Note that the $l_p$ distance of all of these adversarial examples are quite large for every $p$, so large in fact that an $l_p$ ball of this size around the clean examples would contain images of the other classes. As a result further improvements to defenses within the standard rules are unlikely to defend against this attack. One could consider many other kinds of attacks that would achieve the same result, for example complementing the image would fool a classifier not trained for such a transformation [120]. Another example similar in spirit to our background attack is the adversarial patch [105]. We also tried a “lines” attack, where a line of a randomly chosen orientation is applied to the image at random. This attack was quite successful and did not rely on access to model weights,
architecture or training data. In fact, the median number of model queries required to find an error using this attack method was 6. Overall, the space of content-preserving image transformations remains largely unexplored in the literature. A method that is robust to content-preserving image transformations on MNIST requires more than being robust to one specific distribution of images and would be exciting from the standpoint of improving supervised learning even without invoking a security motivation.

Figure 6: There are many ways to perturb an image that preserve semantic content. One example is an “attack” which only modifies unimportant pixels in the background. In another example, the attacker applies a line to the image of a randomly chosen orientation. Note that these attacks are designed to only preserve content. The attacker does not attempt to be subtle or imperceptible in any way and does not restrict themselves to small perturbations in any sense.

If future work wishes to develop strategies to defend a prohibited content classifier against something like the revenge porn attack, it may be an unrealistic assumption that the attacker has full knowledge of the training set and the model. In fact, a social media website might ban an attacker the first time they attempt to upload a pornographic image, so assuming the attacker has only limited query access to the defender’s model might even be reasonable. Social media sites might have policies that let users flag content violating the terms of service to correct algorithmic errors. These policies might make it possible to still deploy weak classifiers and lessen the importance of defending the classifier itself. In order to make the correct assumptions about these sorts of details we have to tie the threat model to the real-world system we want to secure. In describing a realistic threat model we should take the advice from Huang et al. [116] to heart:
Ideally, secure systems should make minimal assumptions about what can realistically be kept secret from a potential attacker. On the other hand, if the model gives the adversary an unrealistic degree of information, our model may be overly pessimistic; e.g., an omnipotent adversary who completely knows the algorithm, feature space, and data can exactly construct the learned classifier and design optimal attacks accordingly. Thus, it is necessary to carefully consider what a realistic adversary can know about a learning algorithm and to quantify the effects of that information.

Exploring robustness to a whitebox adversary in the untargeted content preservation setting should not come at the cost of ignoring defenses against high-likelihood, simplistic attacks such as applying random transformations or supplying the most difficult test cases. A simplistic attacker who applies random noise to the background of an image (or other random content preserving transformations) will already be successful given enough attempts. Simpler attackers can be realistic when real-world attackers do not have ML expertise and look for the easiest way to fool a model. As we discuss in the next section, a more robust way to measure progress against such attackers might be through test error on data augmented with different random image transformations, using hold-out sets of transformations to account for the kinds of attacks a real-world attacker may try against a black-box system. Crucially, successfully defending against a simplistic content preserving transformation attacker is a necessary step towards defending against a sophisticated attacker with whitebox access and the same action space. Work primarily motivated by security should first build a better understanding of the attacker action space. In particular, the space of content preserving image transformations remains largely unexplored in the literature, although the transformations considered in Engstrom et al. [107] and Verma et al. [122] are a good start. By first focusing on simpler attacks, we can avoid the cycle of falsification caused by attempting to measure worst-case $l_p$-robustness empirically and have a more immediate impact on real systems.

### 5.2 A Call For Security-Centric Proxy Metrics

While real-world security concerns, such as “indistinguishable”, “content-preserving”, or “non-suspicious” are the best basis for evaluating security threats against systems, they are also difficult to formalize: there is no obvious function that can determine if a specific transformation is “content-preserving”, or if it has modified the input so much that a human would no longer recognize it. Even if such a function is found, it is still necessary for evaluators to carefully define what the expected distribution of inputs at test time is and justify how sacrificing performance on one data distribution is worth increased robustness to one class of adversarial inputs.

11Outside of the context of perturbation defenses, it has sometimes been found that it is possible to defend against a specific class of random transformations by training on that set of random transformations. For example, neural networks trained on obfuscated text CAPTCHAs can read obfuscated text better than humans [121]. In the future, it may be possible to design more robust benchmarking procedures by evaluating the performance of the model on held-out transformations that were not used during training. This is unlikely to be a panacea against an intelligent adversary, of course: Some experience finds that random perturbations affect model outputs less than adversarial perturbations do [63]. Similarly, training on random perturbations has less of an effect than training on adversarial perturbations [93]. These results suggest that further advances will be needed in order to create improved methods for benchmarking robustness against less-constrained adversaries, as discussed in the following section.
Despite the difficulty of doing so, we believe it would benefit the community greatly to develop a broader set of “proxy metrics” for the security models we outlined in Section 2.

In many real-world settings, content preservation and distinguishability exist on a continuum: at the extreme end, modifications that are indistinguishable are axiomatically content-preserving. More invasive modifications may be increasingly distinguishable, and at some point, begin to degrade measures of content preservation. A cohesive metric or set of techniques for generating adversarial examples at different points on this continuum would be helpful in allowing defense designers to clearly match their defenses with their assumed threat environment. While the $l_p$ metric has been used as a proxy for distinguishability, it is not one grounded in human perception; the available perturbations are artificially restricted if the allowed $l_p$ perturbations are too small, and there is no longer any relationship to human centric measures of content preservation if the perturbations are too large.

Developing such a metric will be challenging — some of our current best proxies for content similarity between images rely on deep neural networks Zhang et al. [123]. Unfortunately, one purpose of developing such a metric is to measure the robustness of these same methods!

A second option that is more pragmatic in the short-term may be to take a constructive approach with hold-out distributions: Establishing families of transformations deemed “content-preserving” or “similarity-preserving”, and holding out one or more such families during training to simulate whether defenses are effective against as-yet-unknown content-preserving transformations. In the previous subsection, we discussed several types of constructive modifications that preserve the content of MNIST digits; these, along with others, could form the basis for a more general, systematic approach to testing robustness to a content-preserving adversary.

Less-constrained attackers, such as non-suspicious or content-constrained attackers, seem so domain-specific that we believe the best approach is first to identify and propose solutions to specific, concrete threats within this domain, before trying to generalize across domains. It is important to remember that the defender might have options available that do not involve “securing” the underlying ML classifier at all, but instead entail adding other mechanisms to the overall system that enhance security. For example, to defend against “hidden voice commands” 83 suggests that designers could modify a device to notify the user any time a voice command is received. The iPhone FaceID unlock improves robustness to certain attacks by using multimodal input: a 3D depth map and a heatmap of the face, in addition to the actual picture of the human face. Improvements to the machine learning classifier may still be useful as defense-in-depth or to improve overall performance, but the severity of a particular threat should be considered in its appropriate context, including defenses outside of the classifier.

We end, however, on a cautionary note: over 18 defenses to restricted white box attackers have been proposed, with “successful” evaluation, only to later be shown ineffective 79 94 95. This is because they relied on limitations in the ability of standard optimization procedures to generate satisfying examples, not upon fundamental restrictions about the space of valid adversarial inputs. Given that empirically evaluating the $l_p$-robustness metric is an NP-hard problem in general, we do not expect this difficulty of evaluating performance to restricted white box attackers will have a comprehensive resolution. This difficulty in evaluation makes measuring generalization out of distribution (as measured by hold-out transformations, or other distributions) a more reliable, if still limited, alternative to evaluating security-centric models than performance on restricted worst-case attacks.
6 Conclusions and Future Work

We should do our best to be clear about the motivation for our work, our definitions, and our game rules. Defenses against restricted perturbation adversarial examples are often motivated by security concerns, but the security motivation of the standard set of game rules seems much weaker than other possible rule sets. If we make claims that our work improves security, we have a responsibility to understand and attempt to model the threat we are trying to defend against and to study the most realistic rules we are able to study. Studying abstractions of a security problem without corresponding applied work securing real systems makes careful threat modeling more difficult but no less essential.

An appealing alternative for the machine learning community would be to recenter defenses against restricted adversarial perturbations as machine learning contributions and not security contributions. Better articulating non-security motivations for studying the phenomenon of errors caused by small perturbations could highlight why this type of work has recently become so popular among researchers outside the security community. At the end of the day, errors found by adversaries solving an optimization problem are still just errors and are worth removing if possible. To have the largest impact, we should both recast future adversarial example research as a contribution to core machine learning functionality and develop new abstractions that capture realistic threat models.
