ACCEPTED MANUSCRIPT

The International Journal of Developmental Biology publishes an “Accepted” manuscript format as a free service to authors in order to expedite the dissemination of scientific findings to the research community as soon as possible after acceptance following peer review and corresponding modification (where appropriate).

An “Accepted” manuscript is published online prior to copyediting, formatting for publication and author proofing, but is nonetheless, fully citable through its Digital Object Identifier (DOI). Nevertheless, this “Accepted” version is NOT the final version of the manuscript.

When the final version of this paper is published within a definitive issue of the journal with copyediting, full pagination, etc. the new final version will be accessible through the same doi and this "Accepted" version of the paper will disappear.
**Cortical Interneuron Development: a role for small Rho GTPases**

**ABSTRACT**

GABAergic interneurons control cortical excitation/inhibition balance and are implicated in severe neurodevelopmental disorders. In contrast to the multiplicity of signals underlying the generation and migration of cortical interneurons, the intracellular proteins mediating the response to these cues are mostly unknown. We have demonstrated the unique and diverse roles of the Rho GTPases Rac1 and 3 in cell cycle and morphology in transgenic animals where Rac1 and Rac1/3 were ablated specifically in cortical interneurons. In the Rac1 mutant, progenitors delay their cell cycle exit probably due to a prolonged G1 phase resulting in a cortex with 50% reductions in interneurons and an imbalance of excitation/inhibition in cortical circuits. This disruption in GABAergic inhibition alters glutamatergic function in the adult cortex that could be reversed by enhancement of GABAergic function during an early postnatal period. Furthermore, this disruption disturbs the neuronal synchronization in the adult cortex. In the double mutant, additional severe cytoskeletal defects result in an 80% interneuron decrease. Both lines die from epileptic seizures postnatally. We have made progress towards characterizing the cell cycle defect in Rac1 mutant interneuron progenitors, determining the morphological and synaptic characteristics of single and double mutant interneurons and identifying some of the molecular players by which Racs exert their actions by proteomic analysis. In our present work, we review these studies and discuss open questions and future perspectives. We expect that our data will contribute to the understanding of the function of cortical interneurons, especially since preclinical models of interneuron-based cell therapies are being established.

**INTRODUCTION**

Gamma-aminobutyric acid-containing (GABAergic) interneurons, although comprising ~20% of all cortical neurons, play important roles in cortical function and have been implicated in severe disorders such as schizophrenia, epilepsy and autism spectrum disorders (Lewis et al.,
Interneurons are characterized by a remarkable morphological, molecular and functional diversity, and recent studies have uncovered some of the molecular components underlying the generation of this diversity (Wonders and Anderson 2006; Kepecs and Fishell 2014; Kessaris et al. 2014). All CINs (Figure 1) originate mainly from the ganglionic eminences, which are well-defined domains of the basal telencephalon, and migrate tangentially to populate the developing cortex (Lim et al., 2018).

Figure 1. GABAergic Interneurons originate from subpallium structures, medial ganglionic eminence (MGE) and caudal ganglionic eminence (CGE). 50-60% of all cortical interneurons originate in the MGE and the main subtypes are the Parvalbumin (PV) and Somatostatin (SST) interneurons. They follow tangential routes towards and inside the pallium in contrast to the pyramidal neurons that move radially within the pallium (Marín and Rubenstein 2001; Corbin et al. 2001; Batista-Brito and Fishell 2009).

Around 60% of CINs are born in the MGE and include two major subtypes, defined by the expression of the calcium binding protein Parvalbumin (PV) and the neuropeptide Somatostatin (SST). At the top of this cascade is the transcription factor Nkx2.1, which is expressed transiently in MGE-derived IN progenitors, followed by the sequential and prolonged expression of LIM homeobox 6 (Lhx6), SRY-box transcription factor 6 (Sox6) and SC35-interacting protein 1 (Sip1) (Lim et al., 2018). Ablation of these transcription factors within CINs, results in multiple defects at several developmental steps, such as migration, laminar acquisition, survival and marker expression, within both CIN subtypes.

The cellular and molecular mechanisms guiding interneurons from their subpallial origins to the cortex have only recently started to be elucidated. The long list of cues involved includes long-range attractive and repulsive factors, surface-bound permissive and instructive molecules and motogenic Factors (Marín, 2013). As part of our studies on the involvement of axon guidance cues in tangential migration, we found that the adhesion molecule transient axonal glycoprotein (TAG-1)/contactin 2 (Cntn2), which is prominently expressed in corticofugal fibers, plays a role as a permissive cue for MGE-derived interneurons to move along these fibers as they enter the cortical area (Denaxa et al., 2005). However, in contrast to the multiplicity of extracellular signals, the intracellular proteins that mediate the response to these cues remain understudied (Peyre et al., 2015) (Figure 2).

The Rac subfamily of Rho-GTPases is a family of proteins involved in a number of cellular functions such as regulation of actin dynamics, cell cycle entry and progression, polarity and axonogenesis (reviewed in (Jaffe and Hall 2005; Koh 2007; Govek et al. 2011). Recent data from our lab demonstrated that the small Rho-GTPases Rac1 and Rac3 have diverse roles as intracellular mediators of CIN migration (Vidaki et al. 2012; Tivodar et al. 2015). We review these data below.
Figure 2. Mechanisms by which intracellular molecules regulate interneuron development/migration/generation of their diversity have not been identified yet. (adapted from (Ayala et al., 2007)) (this figure has been created with BioRender.com).

**RAC1 function in interneurons**

The Rac subfamily consists of three members: Rac1 is ubiquitously expressed, while Rac2 is expressed mostly in the hematopoietic system and Rac3 is highly enriched in the nervous system (Malosio et al., 1997). Disregulated Rho-GTPases and actin cytoskeleton have been correlated with the neuronal migration deficits in Lis1-deficient neurons (Kholmanskikh et al., 2003) and Rac1 is involved in the interkinetic nuclear migration of cortical progenitor cells (Minobe et al., 2009). Rac1, is required for the normal proliferation and differentiation of subventricular zone (SVZ) progenitors and for survival of both ventricular zone (VZ) and SVZ progenitors. Specific inactivation of Rac1 in the VZ of the telencephalon of Rac1fl/fl;Foxg1Tg(Cre) mice shows a wide spectrum of defects that range from severe defects in axonogenesis to perturbation in radial migration of cortical neurons as well as increased cell death of nascent neurons (Chen et al., 2009, Leone et al., 2010). In this mouse line, however, it is hard to distinguish cell autonomous from non-cell autonomous defects (Chen et al., 2007). As Rac1 appears to play a crucial role in different cell biological processes in distinct neuronal populations and, possibly, distinct developmental time windows, and its putative role in cortical interneuron development was unclear, we embarked on a project to specifically ablate Rac1 in this population via Cre/loxP technology. We combined an Nkx2.1-Cre transgenic mouse (Fogarty et al., 2007) with a conditional allele of Rac1 (Walmsley et al., 2003) thus deleting the Rac1 gene in the MGE. The ROSA26fl-STOP-fl-YFP allele was also inserted as an independent marker (Srinivas et al., 2001) to allow visualization of the Rac1-mutant neurons, via yellow fluorescent protein (YFP) expression. Expression of this transgene recapitulates the pattern of expression of the endogenous Nkx2.1 gene and has been previously used to lineally mark MGE-derived cortical interneurons, which can be identified by the expression of calbindin (CB), PV, and SST (Sussel et al. 1999; Fogarty et al. 2007; Wonders et al. 2008; Butt et al. 2008).

Ablation of the Rac1 protein from the MGE of Rac1fl/fl;Nkx2.1Tg(Cre);R26R-YFP+/− animals occurs at embryonic day (E) 12 and by E13.5 no YFP+ MGE-derived cells co-express Rac1 and YFP, as assessed by immunohistochemistry. In E13.5 Rac1fl/fl;Nkx2.1Tg(Cre);R26R-YFP+/− embryos, the migration of MGE-derived interneurons is disrupted since YFP+ cells are found only ventrally with respect to the pallial—subpallial boundary. Consistently, analysis of the expression of MGE-specific interneuronal markers, such as Lhx6 (Lavdas et al. 1999; Cobos et al. 2005; Liodis et al. 2007) and SST as well as glutamic acid decarboxylase 67 (GAD67) mRNA that should mark all GABA+ cells, showed absence of positive cells within the developing neocortex of E13.5 mutant embryos. Although by E16.5 and post natal day (P) 0 some YFP+ cells are found in the developing cortex their numbers are significantly decreased while the majority of them are aggregated ventrally in their place of birth, resulting in a 50% reduction in the number of
GABAergic interneurons found in the mature cortex (Vidaki et al., 2012). Rac1 ablation from the MGE affects all cell populations (such as oligodendrocytes) originating there.

MGE explants were grown ex vivo to analyze the migratory behavior of control and mutant interneurons outside their normal environment. Although the speed of migratory cells of both genotypes were not affected, mutant cells were delayed in their exiting the explant and migrating out. These data indicate that the interneuron defect observed in Rac1 mutant animals is intrinsic to the MGE-derived cells and not due to a secondary defect in the cellular environment. In addition, they suggest that upon deletion of Rac1, the initiation of migration of MGE cells occurs later than in control cases. Importantly, these ex vivo observations correlate with the observed in vivo phenotype, where mutant cells start their migration later than the control ones.

Since the majority of Rac1 mutant animals die at around weaning time, we decided to analyze the brains of postnatal mice at P15. No differences in the overall structure of the brain between control and mutant animals were observed, as assessed by histological staining. The number and distribution of interneurons in the neocortex were examined either by expression of the lineage marker YFP and the general marker GABA or markers that are specifically expressed in MGE-derived interneuronal subpopulations such as Lhx6, PV, and SST. We have also examined calretinin (CR) and neuropeptide Y (NPY) which are primarily expressed by cortical interneurons derived from the CGE (Fogarty et al. 2007; Butt et al. 2008) focusing primarily in the barrel cortex. The quantifications revealed a 50% reduction in MGE-derived interneurons, but the ability of Rac1-deficient precursors to differentiate into different mature interneuron subtypes is not compromised, despite their reduced numbers.

We then assessed the pool size of proliferating progenitors and their mitotic potential in the MGE of control and Rac1 conditional mutant embryos in order to study whether the reduction in the number of cortical interneurons is due to perturbed proliferation in the VZ. No significant differences were observed. Thus, the reduced number of GABAergic cells in the cortex of mutant mice is not due to defective proliferation or aberrant mitotic activity of the Rac1-deficient cells. In addition, we examined apoptotic cell death at several embryonic stages of these animals with no apparent differences. However, we found that inactivation of Rac1 perturbs G1 phase progression and reduces cell cycle exit of MGE-derived progenitors by comparing the cell cycle dynamics of MGE progenitors in the two genotypes. For this, we pulse-labeled neural progenitors with Bromodeoxyuridine (BrdU) at E12.5 and collected the embryos 24 h later for anti-BrdU and anti-Ki67 double-labeling. The fraction of BrdU+ cells that do not express Ki67 (Ki67−) was estimated in the MGE of control and mutant embryos, as well as in the lateral ganglionic eminence (LGE) which served as an internal control. This analysis revealed a specific decrease of BrdU+/Ki67− progenitors from the MGE in mutant embryos, indicating that fewer progenitors had exited the cell cycle in the absence of Rac1. We also found that Rac1 mutant embryos have greatly diminished amounts of phosphorylated Rb, a critical checkpoint of the cell cycle, in their MGE cells, compared with control littermates. We additionally analyzed the levels of cyclin D proteins since cyclins are crucial for phosphorylation of Rb and progression of the cell cycle through the G1 phase. We found a 2-fold reduction in the levels of cyclin D proteins in the MGE of mutant embryos compared with control littermates. Altogether, these data indicate a specific role for Rac1 in the progression of the MGE-derived cells through the cell cycle, possibly during the G1 phase. In addition, a large percentage of Rac1-deficient neurons, most likely the population that remains aggregated in the ventral telencephalon, appear to have affected growth cones and abnormal axon extension, which is consistent with previously reported roles of Rac1 in cytoskeletal dynamics (Jaffe and Hall 2005; Koh 2007; Tahirovic et al. 2010). In short, we established that Rac1 is required cell autonomously for cortical interneuron development and cell cycle progression (Vidaki et al., 2012).

In order to verify the necessity of Rac1 in the Nkx2.1-positive progenitors of the MGE and to exclude an additional essential role for Rac1 in postmitotic cells, we deleted Rac1 specifically in postmitotic MGE-derived interneurons expressing Lhx6 using Lhx6-Cre transgenic mice (Fogarty et al., 2007). No differences in the migratory capacity or eventual numbers in the mature cortex between the two genotypes were observed, indicating that the
requirement of Rac1 activity for the development of cortical interneurons is restricted to the progenitors that reside in the VZ of the MGE (Vidaki et al., 2012).

As mentioned above, mutants die in early postnatal life due to epileptic seizures but some survive till adulthood. We thus turned our attention to the putative adaptations that may occur in the adult glutamatergic system in the presence of a developmental defect in interneurons that does not allow them to reach the cerebral cortex in normal numbers. We used the Rac1 conditional mutant mentioned above to examine how the developmental loss of interneurons may affect basal synaptic transmission, synaptic plasticity and neuronal morphology in the mouse prefrontal cortex (PFC). Despite the 50% decrease in the number of interneurons, basal synaptic transmission, as examined by recording field excitatory postsynaptic potentials (fEPSPs) from layer II networks, is not altered in the PFC of Rac1 mutant mice. However, there is decreased paired-pulse ratio (PPR) and decreased long-term potentiation (LTP), in response to tetanic stimulation, in the layer II PFC synapses of Rac1 mutant mice. Furthermore, expression of the N-methyl-D-aspartate receptor (NMDA) subunits is decreased and dendritic morphology is altered, changes that could underlie the decrease in LTP in the Rac1 mutant mice. Finally, we found that treating Rac1 mutant mice with diazepam in early postnatal life can reverse changes in dendritic morphology observed in non-treated Rac1 mutants. Therefore, our data indicates that disruption in GABAergic inhibition alters glutamatergic function in the adult PFC, an effect that could be reversed by enhancement of GABAergic function during an early postnatal period (Konstantoudaki et al., 2016).

Our work also pointed out at significant alterations in both inhibitory and excitatory systems in the adult barrel cortex (BC) of Rac1 mutant mice (Kalemaki et al., 2018). We investigated the functional changes in adult cortical network activity in response to developmentally reduced inhibition. The decrease in the number of interneurons increased basal synaptic transmission, as examined by recording fEPSPs from layer II networks in the Rac1 mutant mouse cortex, decreased LTP in response to tetanic stimulation but did not alter the PPR. Furthermore, under spontaneous recording conditions, Rac1 mutant brain slices exhibit enhanced sensitivity and susceptibility to emergent spontaneous activity. We also find that this developmental decrease in the number of cortical interneurons results in local neuronal networks with alterations in neuronal oscillations, exhibiting decreased power in low frequencies (delta, theta, alpha) and gamma frequency range (30–80 Hz) with an extra aberrant peak in the high gamma frequency range (80–150 Hz). Therefore, our data show that disruption in GABAergic inhibition alters synaptic properties and plasticity, while it additionally disrupts the cortical neuronal synchronization in the adult BC (Kalemaki et al., 2018).

**RAC1 and RAC3 combined action in interneurons**

As detailed above, Rac1 ablation in interneurons results in 50% reduction of these cells in the mature cortex (Vidaki et al., 2012). We reasoned that other Rho-GTPase proteins may compensate for each other’s function. A microarray-based comparative profiling of gene expression of dorsal forebrain from E15.5 wild-type and Lhx6 mutant mice was carried out to identify novel genes implicated in cortical interneuron development (Denaxa et al., 2012). Among the genes affected by the deletion of Lhx6 in the dorsal forebrain was the Rho-GTPase protein Rac3. Since Lhx6 null mice show defects in the tangential migration of cortical interneurons (Liodis et al., 2007; Zhao et al. 2008), we hypothesized that this might be partially due to the lack of Rac3 protein in Lhx6 mutant interneurons. Nevertheless, Rac3 mutant mice have been reported not to have obvious defects in cortical interneuron migration (Corbetta et al., 2005), in contrast to our studies on the Rac1 mutant. We thus set out to study the role of both Rho-GTPase proteins in cortical interneuron development.

The Rac1 conditional knockout (Rac1fl/fl; Nkx2.1+/Cre, (Vidaki et al., 2012) was crossed to Rac3-deficient mice (Rac3−/−, Rac3KO; (Corbetta et al., 2005). Thus, we obtained a line where cortical interneurons deriving from the MGE are missing both Rac1 and Rac3 proteins (Rac1fl/fl; Rac3−/−;Nkx2.1+/Cre, double mutant) and performed similar studies as described above for the single mutant (Tivodar et al., 2015).
We observed that the double mutant cells entered the dorsal telencephalon ~1 day later than the single Rac1 mutant YFP+ cells. Analysis with a postmitotic marker of MGE-derived GABAergic interneurons, Lhx6, and a subtype specific marker, SST verified the severely reduced number of migrating interneurons at E14.5 in the dorsal telencephalon of the double mutants. Later in embryogenesis (E16.5), in the double mutants, only a few YFP+, Lhx6+, or SST+ cells were found inside the cortex but not extending as dorsally as in control mice. In addition, a significant accumulation of these cells was observed in the ventral telencephalon of double-mutant embryos and not in the control ones.

In the postnatal cortex, the number of MGE-derived GABAergic interneuron subpopulations is severely reduced in the Rac1/Rac3 while their differentiation is unaffected (Tivodar et al., 2015). A striking 80% of YFP+ cells were absent in the double mutant barrel cortex compared with the control one. Given the great loss of interneurons, we decided to look for further abnormalities in the cortices of double mutants. We observed that all layers were present at the correct place, while the cortex width in the double-mutant animals was not significantly smaller compared with control animals. In addition, there was no difference in the cell cycle exit index between the Rac1 conditional mutants and the double mutants, suggesting that this effect is likely due to the absence of Rac1 alone.

Furthermore, the MGE-derived interneurons missing Rac1 and Rac3 have specific morphological defects. Studies with MGE explants comparing control, Rac1 mutant, Rac3 mutant and double mutants showed that the double mutants had significantly shorter neurites and were the least motile, lacking the characteristic growth cone extension/retraction movements. To further study the morphological defects of Rac1/Rac3-deficient interneurons and their intrinsic or extrinsic nature, we grew ventrally aggregated YFP+ cells from the MGE on collagen-coated coverslips. We processed these cultures either for scanning electron microscopy (SEM) analysis or for immunostaining for various cytoskeletal markers. High magnification analysis of these cultures using SEM strongly indicated the presence of morphological defects in the absence of both Rac proteins. These morphological defects included an increased number of neurites per cell, splitting of the leading processes and absence of an obvious axonal growth cone (Tivodar et al., 2015) (Figure 3).

In particular, our data indicate that the stability of microtubules is affected in the double mutant. While the signal of acetylated tubulin (Ac-tubulin), a post-translational modification correlated with stable microtubules, was reduced in western blots, there was a
change in its distribution as in IHC the signal was enriched at the axon initial segment. We treated MGE-derived cells from control and double mutants in culture with taxol, which is known to stabilize microtubules by reducing their dynamics (Etienne-Manneville, 2010). We observed a partial rescue after taxol treatment, assessed by the length and the number of leading processes in the double mutant cultures. Leading process length was increased and the number of processes was reduced in the presence of taxol in cells where both Rac1 and Rac3 proteins were deleted. These findings indicate that Rac proteins are essential for interneuron migration by regulating actin–microtubule dynamics in developing MGE-derived interneurons (Tivodar et al., 2015). In addition, proteins of the PAK-interacting exchange factor (PIX)/G-protein coupled receptor kinase-interacting protein (GIT) network expressed in MGE-derived cells and functionally linked to Rac1/3 have been shown to be involved in proper neuritic development (Franchi et al., 2016).

**Time-lapse studies revealing the migratory behavior of double mutants**

Cortical interneurons undergo a three-step migratory cycle in order to migrate from their birthplace to the neocortex. In the first step the leading process extends and a cytoplasmic swelling appears in the proximal part of it, toward which the centrosome and the Golgi apparatus moves. Secondly, the nucleus translocates forward in a saltatory manner and invades the swelling and last the trailing process is retracted (Bellion 2005; Valiente and Marín 2010). When grown in 2D substrates in vitro, Rac1/Rac3-deficient interneurons show splitting of the leading process, abnormal growth cone, reduction of axon length, and reduction of microtubule stability. Also, in a 3D environment a significant delay in axon outgrowth is observed. Additionally, in Rac1/Rac3-deficient interneurons, the centrosome and Golgi complex positioning are also defective. Subsequently, their migratory behavior in ex vivo time-lapse imaging assays is severely perturbed as several motility parameters (velocity, frequency and amplitude of nuclear translocation) are significantly decreased (ZK and DK, unpublished). The defects in microtubules also affect the lysosomal transport in still extending axons as well as the lysosomal localization in migrating cortical interneurons. RNA seq analysis indicated putative downstream effectors, among them, the two-pore channel protein TPC2, a lysosomal channel responsible for the endo-lysosomal calcium release, which is implicated in metastatic cell migration (Nguyen et al., 2017). In Rac1/Rac3-deficient interneurons TPC2 levels are reduced and the protein distribution is altered. Pharmacological inhibition of the channel affects negatively axon outgrowth of wild type CINs and also results in defective migration in ex vivo time-lapse imaging experiments (ZK and DK, unpublished). These findings indicate, once again, the requirement of Rac protein in regulating cytoskeletal dynamics during cortical interneuron migration and also provides additional evidence that migrating cells utilize similar mechanisms in order to move, independent of their cell identities per se (i.e. cancer cells and neurons). (Figure 4)
Unanswered questions and future perspectives

Despite our progress to understand the function of Rho GTPases in interneuron development, several questions remain unanswered. A major challenge is to uncover the exact molecular mechanism via which the specific defects occur in the Rac1 single mutant line as well as the Rac1/3 double mutant line we have generated. As it pertains to the prolonged G1 phase that we uncovered in the Rac1 mutant, we need to be able to observe individual cells. However, due to the high density of the ventrally aggregated cells, it was not possible to study the morphological features and proliferative dynamics of cycling progenitors. These can be labelled in utero with low titer replication-incompetent, CRE-dependent, fluorophore-expressing retroviruses to uncover the cell division profiles of mutant progenitors and intermediate-progenitors *in vivo*. In addition, using the same viruses we can infect cells in organotypic brain slices *ex vivo* and examine the division patterns of these progenitors by monitoring their cell divisions by time-lapse microscopy.

An additional question worth investigating is the status of individual CINs (Rac1 and Rac1/3 mutants) and whether they are properly integrated in the mature cortical circuits. Although the majority of both mutant mice die before weaning at early postnatal stages, a small percentage of them survive until at least 3 weeks after birth. Therefore, it is possible to investigate the morphological and functional properties of the remaining CINs in the brain for both Rac1 and Rac1/3 deficient mice, in order to identify additional cellular processes that Rac1 and Rac3 proteins are implicated. These experiments can be performed by injecting CRE-dependent fluorophore-expressing adeno-associated viruses and examine the brains a few weeks later for whole neuron morphology (dendritic growth and patterning) as well as dendritic spine and synaptic puncta analysis. In addition, with the same approach, we can investigate whether any defects we can discern are cell autonomous or not, by transplanting mutant labelled cells intracranially into wild type brains and vice versa (Denaxa *et al.*, 2019). In this way, we can enforce the mutant cells to find themselves in a wild type environment and assess their morphological properties. For the functional analysis, mutant interneurons can be subjected to patch-clamp recordings. Intrinsic electrophysiological properties via whole-cell patch-clamp in current-clamp mode, including passive and active properties, can be studied. Via whole-cell patch-clamp in voltage-clamp mode, the spontaneous excitatory and inhibitory post-synaptic currents (EPSCs and IPSCs) can be obtained, as a result of input by presynaptic neurons.

Furthermore, it is important to determine which is the role of Rac1 and Rac3 proteins in the development of synapse formation in CINs, as studies point to the involvement of Racs in synaptogenesis and dendritogenesis in other neurons (Tolias *et al.* 2005; Corbetta *et al.* 2009; Um *et al.* 2014; Zamboni *et al.* 2016; Nakamura *et al.* 2017; Tu *et al.* 2020). CRE-dependent fluorophore-expressing adeno-associated viruses can be used to infect mixed cortical cultures and measure the synapse density, by quantifying co-localized puncta of pre- and postsynaptic excitatory or inhibitory synaptic markers that overlap with labeled interneurons.

Finally, a quantitative proteomic analysis in GFP+ CINs from the single Rac1 mutant could be undertaken to reveal up or downregulated effectors, in addition to a phosphomics approach to detect post-translational modifications. Determining a set of phosphorylated proteins that might be altered in the absence of the Rac1 protein, could give us important information about the signaling pathways that are active under this condition. Providing such a candidate list will enable us to test the top choices in brain slices and see whether we can rescue the migratory defects by overexpressing these candidate molecules.

In conclusion, the two genetic models we have generated have been useful in understanding novel aspects of interneuron development and the involvement of Rho GTPases in this process. These new data, will not only contribute with novel information...
about the development of cortical assemblies but, in combination, will provide insight for unique neuron-type defects to specific neurodevelopmental diseases.
