Disordered insulating materials often have randomly placed electric or magnetic dipoles that have long range dipolar interactions. Examples include impurities in alkali halides that can be used for paraelectric cooling \[1, 2\], diluted ferroelectric materials \[3\], disordered magnetic materials, and frozen ferrofluids \[4\]. These systems are typically modeled as spin glasses that have simpler interactions and yet are believed to capture the essential physics of interacting dipoles. Based on theoretical studies of spin glasses with long range interactions \[5, 6, 7, 8\], one would expect dilute Ising dipolar systems to undergo a spin glass-like transition as the temperature decreases. However, in this paper we find the surprising result that, unlike the three dimensional Ising spin glass with \(1/r^3\) interactions \[5, 6\], dilute Ising dipolar systems do not undergo a phase transition as the temperature decreases. This may explain the lack of experimental evidence for such a transition in very dilute systems.

An example of dipoles is two level systems (TLS) that dominate the physics of glasses at low temperatures \[10\]. TLS often have randomly oriented electric dipole moments that interact through an elastic strain field with a long range interaction that is a stress tensor generalization of the vector dipolar interaction \[11\]. While there have been experimental hints of a spin glass transition among TLS in glasses at low temperatures \[12\], there has been no definitive experimental proof that such a transition occurs. Since the estimated concentration of TLS is low (100 ppm), our result may explain the absence of a transition even though TLS dipoles are randomly oriented and may not be Ising.

Another example is the insulator LiHo\(_x\)Y\(_{1-x}\)F\(_4\) \[13\] in which the holmium ions have Ising magnetic dipole moments that lie along the z-axis due to crystal field effects \[14\]. For very dilute systems \((x = 4.5\%)\) LiHo\(_x\)Y\(_{1-x}\)F\(_4\) shows no sign of a transition \[15\]. The lack of low temperature freezing in LiHo\(_x\)Y\(_{1-x}\)F\(_4\) has been attributed to dominant quantum mechanical effects in the so-called spin liquid or antiglass phase \[15, 16\]. However, a theoretical investigation of whether or not classical interacting dipoles undergo a spin glass phase transition at low concentrations has been lacking. Several previous studies of dipolar interactions between randomly placed Ising dipoles have focussed on the ferromagnetic transition that occurs at higher dipole concentrations \[3, 7, 8\]. Monte Carlo simulations have looked at intermediate concentrations with \(x \geq 25\%\) where there is a spin glass transition \[7, 12\]. Xu et al. \[7\] used mean field theory and found, depending on the lattice structure, ferromagnetic or antiferromagnetic transitions at higher concentrations. They found a spin glass phase at lower spin concentrations but the properties of this phase were unreliable because they had a replica symmetric solution. In short, there have been no definitive theoretical studies of the very dilute classical cases. In this paper we present the results of Wang-Landau Monte Carlo simulations on classical dilute Ising dipolar systems in three dimensions. We find that there is no phase transition for low concentrations in qualitative agreement with experiment.

In spin glasses the distribution \(P(q, T)\) of the overlap order parameter \(q\) changes from being a Gaussian centered at \(q = 0\) at high temperatures to a bimodal distribution with peaks at \(q = \pm 1\) at low temperatures. At intermediate temperatures it is relatively flat. We can define a characteristic glass transition temperature \(T_g\) as the temperature where \(P(q, T)\) is the flattest. In the thermodynamic limit we find that for a given dipole concentration \(T_g\) goes to zero as \(1/\sqrt{N}\) where \(N\) is the number of dipoles. Also, we examine the entropy and find that for concentrations less than 20\% there is a nonzero entropy per dipole as \(T \to 0\). The entropy and lack of a transition are consistent with a large number of accessible low energy states and glassy behavior.

We consider Ising dipoles randomly placed on a simple cubic lattice at concentrations of \(x = 4.5\%, 12\%,\) and 20\%. The interaction between any two dipoles \(\vec{p}_1\) and \(\vec{p}_2\) separated by a vector \(\vec{r}_{12}\) is given by the Hamiltonian:

\[
H(\vec{p}_1, \vec{p}_2) = \frac{\vec{p}_1 \cdot \vec{p}_2 - 3(\vec{r}_{12} \cdot \vec{p}_1)(\vec{r}_{12} \cdot \vec{p}_2)}{r_{12}^3}. \tag{1}
\]

In addition to the energy units set by \(H\), the units are set by \(\vec{p}_i = \pm \hat{z}\), the lattice constant \(a = 1\), and Boltz-
mann’s constant $k_B = 1$. These will be referred to as MC units where appropriate. We use the Ewald summation technique to handle the long range nature of the dipole interactions \cite{24}. For $x = 4.5\%$, the lattices had $L^3$ sites with $L = 6, 8, 10, \text{and } 12$, and for $x = 12\%$ and $20\%$, $L = 4, 6, \text{and } 8$. The number of dipoles $N$ is the smallest even integer greater than or equal to $xL^3$.

The glassy energy landscape at low concentrations makes it difficult to equilibrate at low temperatures with the traditional Metropolis Monte Carlo approach. To overcome this, we have used the Wang-Landau (WL) Monte Carlo technique \cite{21} to calculate the density of states $n(E)$ where $E$ is the energy of the system. Briefly, this algorithm starts with an initial guess $n(E) = 1$ and executes a weighted random walk on the energy landscape. Single flips of randomly selected dipoles are then accepted with a probability of $\min[1, n(E_i)/n(E_f)]$ where $E_i$ and $E_f$ are the energies before and after the trial flip. If a step is accepted (rejected), then the density of states is updated by the rule $n(E_{f(i)}) \rightarrow \gamma n(E_{f(i)})$ where $\gamma > 1$ is a scale factor. A histogram of the visited energies $h(E)$ is recorded. The criterion for a satisfactory estimate of the density of states is given by the flatness of $h(E)$, i.e., $h(E) > \epsilon(h)$ for every energy $E$ where $0 < \epsilon < 1$ determines the accuracy; typically, $\epsilon \approx 0.95$. Once the flatness condition is satisfied, the scale factor is set closer to 1 by the rule $\gamma \rightarrow \sqrt{\gamma}$, $h(E)$ is reset to zero, and the algorithm is repeated. In all cases, we ran 20 iterations with $\gamma$ starting at $\epsilon$ and ending at 1.0000019, and $n(E)$ was normalized such that $\sum_E n(E) = 2^N$.

The dipolar interaction is nearly continuous so each energy bin may contain multiple states. We choose the bins to be as small as possible while maintaining reasonable computational times. The bin sizes depend on concentration and system size. The bins are about 0.01 in units of energy per particle for 20% filling and 0.001 for 4.5% and 12%. The lowest temperature studied ($T = 0.05$) must be larger than the largest bin (0.02). We try to keep the bins small enough so that $n(E_0) \approx 2$, where $E_0$ is the energy of the (degenerate) ground state. In all cases except one $n(E_0) \approx 3.5$. The exception ($8^3$ at 20%) has $n(E_0) \approx 10$, so we discard the low temperature values of this system.

We average over disorder by having different runs correspond to different quenched placements of dipoles with random initial orientations. The dipoles are fixed in position but not in orientation. There are about 1000 runs for each $x$ and $L$. As a check of our Wang-Landau procedure, we were able to enumerate all the states for 1000 different configurations for concentrations of 4.5% ($L = 6$ and 8), 12% ($L = 4$) and 20% ($L = 4$) and determine the exact density of states. We found very good agreement with our WL results.

Since we are looking for a spin glass phase, we define a generalized Edwards-Anderson overlap order parameter $q = \frac{1}{N} \sum_i \vec{\rho}_{i} \cdot \vec{\rho}_{i}^*$, where $\vec{\rho}_{i}^*$ is a dipole in the state of the current system, and $\vec{\rho}_{i}$ is a dipole in a low energy state found in a short, initial simulation \cite{22, 23}. Then, to find the distribution $P(q,E)$, $q(E)$ is recorded and stored in a histogram during the simulation at the smallest scale factor where the estimate of the density of states is quite good. $P(q,T)$ is calculated as

$$P(q,T) = C_T(1/Z) \sum_E n(E)P(q,E)\exp(-E/kT)$$

where the sum is over all the energy bins and $Z(T) = \sum_E n(E)\exp(-E/kT)$. $C_T$ enforces normalization such that $\sum_q P(q,T) = 1$ for every $T$.

It has often been convenient to find the spin glass transition temperature using Binder’s $g = \frac{[3 - \langle \langle q^4 \rangle / \langle q^2 \rangle^2 \rangle] / 2,}{\langle q^4 \rangle = \sum_q q^4 P(q,T)}$. Since the ground state estimate is not the true ground state, we eliminate all runs in which $g < 0.8$ at the lowest temperature. If there is a second order phase transition, plots of $g$ versus $T$ for different size systems will cross at the transition temperature \cite{22}. However, we find that these curves do not cross, so there is no second order spin glass phase transition.

To investigate this further, we can look at how $P(q,T)$ changes with temperature. For a system undergoing a phase transition, we expect $P(q,T)$ to change from being a Gaussian centered at $q = 0$ at high temperatures to a bimodal distribution with peaks at $q = \pm 1$ at low temperatures. A typical example is shown in Figure 1 for $x = 4.5\%, L = 10$. We define a characteristic “glass” temperature $T_g$ as the temperature where the distribution $P(q,T)$ is flattest. We define the deviation $D(T)$

![Figure 1](image-url)
FIG. 2: Deviation from flatness of $P(q, T)$ for $x = 4.5\%$ with sizes $L = 6^3, 8^3, 10^3,$ and $12^3$. The minima move left with increasing size and defines a glass transition temperature. The plots for $x = 12\%$ and $20\%$ are similar.

from flatness in terms of the variance of $P(q, T)$ as

$$D(T) = L^3 \left\langle \left( P(q, T) - \left\langle P(q', T) \right\rangle_q \right)^2 \right\rangle_q$$

where $\langle \ldots \rangle_q$ indicates an average over all $N + 1$ possible values of $q$. $D(T)$ is at a minimum when a plot of $P(q, T)$ versus $q$ is the flattest, defining $T_g$. A sample $D(T)$ is plotted in figure 2. For a given dilute concentration, $T_g$ is tending to smaller temperatures as the system size increases which is consistent with $T_g \to 0$ as $L \to \infty$. To find the dependence of $T_g$ on the number $N$ of dipoles for a fixed concentration, we plot the minimum of $D(T)$ versus $N$ in figure 3. The best fit for dilute cases reveals that $T_g \sim N^{-1/2}$. In contrast, $D(T)$ for the ordered case ($x = 100\%$) yields a nonzero transition temperature independent of $N$.

The presence of a transition is consistent with the experimental finding that for very dilute systems ($x = 4.5\%$) LiHo$_2$Y$_{1-x}$F$_4$ shows no sign of a transition. However, the absence of a transition in dilute dipolar systems is unexpected since 3D Ising spin glasses with $1/r^3$ interactions undergo a phase transition. $P(q)$ for a spin glass and for a dilute dipolar system are different; in the thermodynamic limit as $T \to 0$, $P(q)$ for a spin glass has a few sharp peaks corresponding to ground state configurations separated by high barriers, while $P(q)$ for the dilute dipolar system is flat, indicating numerous accessible low energy states separated by insignificant barriers. With very low barriers, states at both the top and bottom of the barrier contribute low energy states. The difference in barrier heights may be due to every site in a model spin glass being occupied so that in a spin glass with power law interactions nearby spins will tend to have stronger interactions than distant spins and produce large barrier heights. In a dilute dipole system nearby sites are empty and so the low energy configurations are determined by distant dipoles which interact weakly and produce low barriers.

The presence of many nearly degenerate accessible ground states is reflected in the finite entropy per dipole near $T = 0$. We find that the low temperature entropy is larger for the lower concentration. We can calculate the total entropy $S_{tot}(T)$ directly from the density of states obtained by our WL Monte Carlo simulations:

$$S_{tot}(T) = \frac{\langle E(T) \rangle}{T} + \log Z(T)$$

where $\langle E(T) \rangle$ is the average energy of the system. $S_{tot}$ is an absolute entropy and is not defined relative to some reference value. To compare different system sizes, we consider the entropy per particle $S_N = S_{tot}/N$ where $N$ is the number of dipoles. The entropy is very smooth, corresponding to a broad bump in the specific heat.

To determine the entropy in the thermodynamic limit, we plot $S_N(T)$ versus $1/N$ at a given temperature $T$. We fit a line to the data and then extrapolate to $N \to \infty$. Then, we plot the extrapolated value versus temperature (see Figure 4). From Figure 4 it is clear that the 4.5% and 12% cases have a nonzero entropy at low temperatures, but the 20% case is approaching zero. Finally, the
extrapolated values are fit with a power law of the form $AT^\lambda + S_o$, where $A$ and $\lambda$ are constants, and $S_o$ is a constant representing the zero temperature value of the entropy. The fit values are $A = 1.1 \pm 0.2$, $\lambda = 2.7 \pm 0.1$, and $S_o = (7.9 \pm 0.3) \times 10^{-3}$ at 4.5%, $A = 1.2 \pm 0.3$, $\lambda = 2.9 \pm 0.2$ and $S_o = (5.6 \pm 0.3) \times 10^{-3}$ at 12%, and $A = 0.37 \pm 0.05$, $\lambda = 1.9 \pm 0.1$ and $S_o = (-0.5 \pm 0.5) \times 10^{-3}$ at 20%.

Note, the extrapolation at 20% gives a negative $S_o$, so it is zero; no actual data points have negative entropy. A phase diagram of the entropies at zero temperature is constructed in the inset of Figure 4. Notice that the low temperature entropy increases as the concentration decreases. This indicates that there are more accessible low energy states in systems with lower concentrations where the dipoles interact more weakly. Having a finite value of $S_o$ implies that the zero temperature entropy $S(0)$ may be nonzero, but this is not unprecedented for a classical system, e.g., noninteracting spins.

We do not think that the finite entropy near $T = 0$ is due to the finite size of the energy bins. To test the effect of the bin size, we halved the bin size (doubled the number of bins) for the case of $6^3$ at 20% and found an entropy change of about 5% which is consistent with the error estimates. We also ran the largest exact case ($8^3$ at 4.5%) through the WL algorithm with bins of width 0.005, and found a change of 0.9% compared to the exact result with zero bin width.

To summarize, we find the surprising result that at low concentrations ($x \leq 20\%$) there is no spin glass-like phase transition as the temperature is lowered. This is consistent with having a large number of nearly degenerate accessible low energy states. Our result could explain the lack of experimental evidence for a transition in LiHo$_x$Y$_{1-x}$F$_4$ for small $x$ and among two level systems in glasses at low temperatures. Thus, contrary to widely held notions, materials with dilute electric or magnetic dipoles cannot necessarily be modeled as spin glasses with long range interactions.

We thank Stuart Trugman and Manoranjan Singh for helpful discussions. This work was supported by DOE grants DE-FG03-00ER45843 and DE-FG02-04ER46107.

---

FIG. 4: Entropy per particle extrapolated to infinite size. From top to bottom the fillings are 4.5%, 12%, and 20%. The curve on the far right is for 100%. The error bars shown represent the standard error ($\sim 10^{-3}$) of the distribution of $S(T)$. Inset: Entropy at $T = 0$ phase diagram. The hashed area is classically not accessible. The solid line is a guide to the eye. Above 20% $S(T = 0)$ is zero.
