Acute myeloid leukemia (AML) is a heterogeneous disease whose prognosis is mainly related to the biological risk conferred by cytogenetics and molecular profiling. In elderly patients (>60 years) with normal karyotype AML miR-3151 have been identified as a prognostic factor. However, miR-3151 prognostic value has not been examined in younger AML patients. In the present work, we have studied miR-3151 alone and in combination with BAALC, its host gene, in a cohort of 181 younger intermediate-risk AML (IR-AML) patients. Patients with higher expression of miR-3151 had shorter overall survival (P = 0.0025), shorter leukemia-free survival (P = 0.026) and higher cumulative incidence of relapse (P = 0.082). Moreover, in the multivariate analysis miR-3151 emerged as independent prognostic marker in both the overall series and within the unfavorable molecular prognostic category. Interestingly, the combined determination of both miR-3151 and BAALC improved this prognostic stratification, with patients with low levels of both parameters showing a better outcome compared with those patients harboring increased levels of one or both markers (P = 0.0003). In addition, we studied the microRNA expression profile associated with miR-3151 identifying a six-microRNA signature. In conclusion, the analysis of miR-3151 and BAALC expression may well contribute to an improved prognostic stratification of younger patients with IR-AML.

Blood Cancer Journal (2015) 5, e352; doi:10.1038/bcj.2015.76; published online 2 October 2015

INTRODUCTION

The biological heterogeneity of acute myeloid leukemia (AML) results in a markedly diverse prognosis and highly differential sensitivity to current standard therapy. The most accurate prognostic stratification is based on cytogenetics, further refined with the analysis of several gene mutations.1–4 In cytogenetic intermediate-risk AML (IR-AML), comprising ~50% of all AML patients, the mutational status of NPM1, internal tandem duplication of FLT3 (FLT3-ITD), and CEBPA defines molecular subcategories with different biological risk and diverse outcomes.5,4 Therefore, many current AML treatment protocols adapt their therapeutic algorithm to this biological risk. Nonetheless, despite several attempts to fine-tune stratification based on these molecular subcategories, the prognosis of many patients with IR-AML is still uncertain and the optimal post-remission therapy is unclear. Several studies have shown the importance of microRNA (miRNA) deregulation in AML.5–7 Distinctive miRNA profiles have been associated with specific cytogenetic subtypes: AML associated with translocation t(8;21), t(15;17) or inv(16) and MLL-rearranged AML,8,9 t(8;16) AML,10 and AML with specific gene mutations,11 including NPM1,9,12 FLT3-ITD,13 and CEBPA.8,10,13–15 In addition, several miRNAs have been associated with clinical outcome.11 Three studies that included cytogenetically heterogeneous AML cohorts found that expression levels of miR-191 and miR-199a,13 miR-196b16 and miR-212 were associated with overall survival (OS). In patients with cytogenetically normal AML (CN-AML) and high-risk molecular features, a 12-miRNA prognostic signature was proposed by the CALGB group; this signature included five members of the miR-181 family.13 The individual prognostic value of miR-181a was later confirmed in a cohort of CN-AML patients by the same group.17 miR-155 has also been

miR-3151 is a prognostic marker in IR-AML

M Díaz-Beyá et al

Blood Cancer Journal

miR-3151 is described as a prognostic marker in both older and younger CN-AML patients by the CALGB group.18 Our group has reported four miRNAs (miR-196b, miR-644, miR-135a and miR-409-3p) with prognostic value in IR-AML.19

miR-3151, which was first identified by massive sequencing techniques,20,21 is located within the first intron of the BAALC gene. In a CALGB study including only CN-AML patients older than 60 years, miR-3151 was identified as an independent prognostic factor.22 In the same study, patients with overexpression of both miR-3151 and BAALC had the worst outcome, while those with low levels of both had the best outcome. Moreover, the authors described an mRNA/miRNA profile associated with higher miR-3151 expression. The same group later reported that miR-3151 and BAALC were both regulated by SP1/NF-KB, while BAALC expression (but not miR-3151) was regulated by the transcription factor RUNX1. Moreover, TP53 was identified as a target of miR-3151, and higher levels of miR-3151 induced leukemogenesis in a murine model and reduced apoptosis and chemosensitivity in AML cell lines.23

Although the CALGB study included only older patients with CN-AML,21 grouping patients with CN-AML together with those with other cytogenetic intermediate-risk alterations in the same prognostic category seems to be warranted from the clinical standpoint.2 Furthermore, younger patients have diverse options for post-remission strategies, including the possibility of an allogeneic hematopoietic stem cell transplantation, depending on biological risk, highlighting a need for prognostic markers in this group. Nevertheless, the prognostic value of miR-3151 expression has not been explored in younger IR-AML patients. We have examined the effect of miR-3151 expression in 181 patients with all types of cytogenetic IR-AML and correlated our findings with outcome.

SUBJECTS AND METHODS

Patients and treatment

We selected patients with untreated, de novo IR-AML according to the MRC classification and with available RNA samples at diagnosis for miRNA analysis (Table 1). All patients provided their written informed consent in accordance with the Declaration of Helsinki, and the Ethics Committee of Hospital Clinic of Barcelona approved the study. All 181 IR-AML patients were treated from 1994 to 2009 in any of 16 centers participating in three consecutive trials of intensive chemotherapy for fit patients of the Spanish AML cooperative group CETLAM: AML-94 (n = 9); AML-99 (NCT01716793) (n = 26); AML-03 (NCT01723657) (n = 146). Briefly, the induction regimen of AML-94 was ICE (idarubicin, standard-dose cytarabine and etoposide), while in AML-99 and AML-03 it consisted of one or two courses of IDICE (idarubicin, intermediate-dose cytarabine and VP-16), with or without priming with G-CSF, respectively. All patients achieving complete remission (CR) received an additional course of chemotherapy with mitoxantrone and high-dose cytarabine, and then a transplant decision was made. In protocols AML-99 and AML-03, an autologous H SCT was planned for patients harboring a normal karyotype without additional risk factors, whereas alloH SCT in first CR (CR1) was recommended for the remaining patients with an available donor. Risk factors considered for risk assignment were the need for two induction courses to achieve CR, detectable minimal residual disease by flow cytometry after intensification therapy (AML-03), and presence of FLT3-ITD (AML-03). In AML-94, post-remission strategy (autoH SCT vs alloH SCT) depended exclusively on the availability of an HLA-identical sibling.

Molecular analysis

NPM1 and FLT3-ITD mutations were assessed on genomic DNA as previously described24-25 with labeled primers and analyzed by fragment analysis (3130XL Genetic Analyzer, Applied Biosystems (AB), Foster City, CA, USA). CEBPA mutations were analyzed as previously described.14,26

Table 1. Main clinical characteristics of patients included in the study

| Intermediate risk AML n = 181 |
|--------------------------------|
| **Year of diagnosis (range)** | 1994–2009 |
| **Gender n (%)**               |            |
| Male                           | 97 (54%)   |
| Female                         | 84 (46%)   |
| **Median age, years (range)**  | 51 (18–69) |
| **Leukocyte count at diagnosis, x 10^9/l median (range)** | 47 (1–408) |
| **FAB subtype (n)**            |            |
| M0                             | 7          |
| M1                             | 53         |
| M2                             | 22         |
| M4                             | 48         |
| M5                             | 37         |
| M6                             | 6          |
| M7                             | 2          |
| **Cytogenetics n (%)**         |            |
| Normal                         | 131 (72%)  |
| Other intermediate-risk        | 50 (28%)   |
| **Molecular features n (%)**   |            |
| NPM1 mutation                   | 79 (43%)   |
| FLT3-ITD                       | 68 (37%)   |
| CEBPA biallelic mutation       | 8 (7%)     |
| **Therapeutic protocol (CETLAM group)** |        |
| AML-94                         | 9 (5%)     |
| AML-99                         | 26 (14%)   |
| AML-03                         | 146 (81%)  |
| **Outcome**                    |            |
| Complete response to induction regimen | 83%       |
| Overall survival (5-year)      | 42 ± 7%    |
| Leukemia-free survival (5-year)| 42 ± 8%    |
| Cumulative incidence relapse (5-year) | 45 ± 8%   |
| Allogeneic H SCT in first CR   | 42 (23%)   |

Abbreviations: AML, acute myeloid leukemia; CR, complete remission; H SCT, hematopoietic stem cell transplantation.

DNA extraction

Samples were obtained from bone marrow aspirates in 171 (94%) patients, and from peripheral blood, with a minimum blast infiltration of 80%, in the remaining 10 patients. Mononuclear cells were purified by Ficoll density gradient centrifugation and total RNA was isolated using Trizol reagent according to manufacturer’s protocol (Invitrogen, Paisley, UK). All patients provided their written informed consent in accordance with the Declaration of Helsinki, and the Ethics Committee of each participating institution approved the study.

miRNA quantification

The expression of miR-3151 was analyzed using TaqMan MicroRNA Assay (Applied Biosystems 243597_mat). Ten nanograms of total RNA were used for miRNA quantification. TaqMan microRNA assays (AB) for miR-3151 were used as previously described27 in an AB 7500 Sequence Detection System. Relative quantification was calculated using 2-ΔΔCt. normalization was performed with RNU48 (Applied Biosystems 4427975). All experiments were performed in triplicate.

We had previously performed a comprehensive miRNA expression analysis, comprising 670 mature human miRNAs, in tumor samples from the 78 out of the 181 patients16 using TaqMan Array Human MicroRNA Set Cards v2.0 (AB).

miRNA expression analysis

cDNA was synthesized from 1000 ng of total RNA using TaqMan Reverse Transcription Reagent Kit (Applied Biosystems). TaqMan Gene expression assays (Applied Biosystems) were used to determine miRNA levels of BAALC.
Molecularly defined prognostic subgroups in IR-AML

The presence or absence of FLT3-ITD, NPM1 and biallelic CEBPA mutations have a strong prognostic impact in patients with IR-AML.3,4 According to the European LeukaemiaNet prognostic classification, patients with the NPM1 mutation or the biallelic CEBPA mutation but without the FLT3-ITD mutation, when associated to normal cytogenetics, comprise a favorable genetic group—with better prognosis—while patients with the FLT3-ITD mutation and/or without the NPM1 and the biallelic CEBPA mutation comprise the intermediate-I and intermediate-II genetic groups. In the present study, we have classified all IR-AML patients with NPM1 mutations or biallelic CEBPA mutations but without FLT3-ITD mutations as the favorable molecular (FAVmol) subgroup and all remaining IR-AML patients as the unfavorable molecular (UNFAVmol) subgroup.

Clinical endpoints and statistical methods

Expression levels of miR-3151 and BAALC were correlated with patient outcome. OS was calculated from diagnosis to death or last follow-up and leukemia-free survival (LFS) from CR to relapse or death. Both OS and LFS were estimated with the Kaplan–Meier method and comparisons among subgroups of patients were performed using the log-rank test. Relapse risk was calculated from CR to relapse and estimated using the cumulative incidence of relapse (CIR) method computed with the cmprsk package for R 2.12 software (The R Foundation for Statistical Computing, http://www.R-project.org/). The competing event in the relapse risk analysis was death without relapse. Comparison of relapse risk between groups of patients was performed using the Gray test.25 Characteristics between groups were compared using the χ2 test and Fisher’s exact test, when applicable, for categorical variables, and the t-test for continuous variables. Multivariate analyses for OS and LFS were performed using the Cox proportional hazards model including age (10-year intervals), gender, white blood cell count (WBC; 50 × 10⁹/l increments) at diagnosis, mutational status of NPM1 and FLT3-ITD, and miR-3151 and/or BAALC expression level. A multivariate analysis for CIR was performed using the subdistribution regression model of Fine and Gray26 with the cmprsk package. The proportional hazard assumption was tested for each variable by analyzing the Schoenfeld residuals. Kaplan–Meier survival curves were then drawn for miR-3151 and BAALC expression predicted to show a survival risk either above or below average risk, using the cut-off points of miR-3151 and BAALC expression levels identified by MaxStat package of R software (The R Foundation for Statistical Computing. http://www.R-project.org/). All analyses were performed with SPSS v20 (Chicago, IL, USA) or R software version 2.12.2 (The R Foundation for Statistical Computing, http://www.R-project.org/). Significance was set at <0.05.

To identify miRNAs with significant differential expression correlated with miR-3151 expression, data obtained from our previously identified miRNA profile13 were analyzed using BRB Array Tools version 3.5.0 software (Richard Simon & BRB-ArrayTools Development Team, http://linus.nci.nih.gov/BRB-ArrayTools.html, National Cancer Institute, Bethesda, MD, USA) and TIGR Multiexperiment viewer version 4.0 software (The Institute for Genomic Research, and ArrayAssist software, Stratagene, http://www.tm4.org/mev; Boston, MA, USA). A student’s t-test based on multivariate permutation was performed with adjustment for multiple comparisons and with random variance model. Differences between miRNAs were considered statistically significant if the P-value was < 0.01.

RESULTS

miR-3151 expression and clinical and molecular characteristics

miR-3151 was expressed with a variable expression level in the group of AML samples analyzed, with a median expression level of 3.94 (0–9.78) (Figure 1). The expression of miR-3151 was not significantly associated with any particular clinical feature, including age, WBC, bone marrow blast proportion, or FAB subtype, with the exception of NPM1 mutation. Thus, miR-3151 was more expressed among patients without NPM1 mutation and, using the same cut-off level as identified by the MaxStat package for prognostic purposes, patients with higher miR-3151 were more likely to harbor a wild-type NPM1 configuration (80 vs 20%, P = 0.009).

miR-3151 expression has independent prognostic value in younger IR-AML patients

With a median follow-up of 8.4 years (range: 36–196 months) among patients alive at last follow-up, the 181 IR-AML patients had a CR rate of 83% and a 5-year OS, LFS and CIR of 42.7 ± 2, 42.8 ± 45 and 45 ± 8%, respectively. Figure 1a shows the optimal cut-off level for miR-3151 expression as identified by the MaxStat package. Patients with higher miR-3151 levels experienced a worse outcome, with poorer OS and LFS (5-year OS: 15 ± 13 vs 46 ± 7%, P = 0.0025; 5-year LFS: 22 ± 18 vs 45 ± 7%, P = 0.026), and a higher CIR (71 ± 20 vs 41.5 ± 8%, P = 0.082) compared with patients with lower levels (Figures 1b–d). In contrast, miR-3151 expression levels were not associated with the probability of attaining CR (83 vs 83%, P > 0.99). Moreover, the proportion of patients who received an alloHCT CR1 did not differ according to miR-3151 expression levels (n = 4 (15%) vs n = 38 (24%)) in patients with high and low miR-3151 levels, respectively, (P = 0.45).

A multivariate analysis confirmed high miR-3151 expression as an independent adverse prognostic factor for OS (OR: 2.97; 95% CI: 1.78–4.93; P < 0.001) and LFS (OR: 2.65; 95% CI: 1.43–4.90; P = 0.002) in addition to other variables with prognostic value such as age (OS, LFS), WBC count at diagnosis (OS), presence of FLT3-ITD (OS), and NPM1 mutations (OS, LFS) (Table 2).

Higher miR-3151 expression was associated with worse prognosis in both favorable and unfavorable molecular subgroups

We then analyzed the specific impact of miR-3151 expression on outcome in the molecularly defined subgroups (FAVmol and UNFAVmol). Among the 128 patients in the UNFAVmol subgroup, high miR-3151 expression identified a subset of patients with a very poor prognosis, with a shorter OS (5-year OS: 6 ± 10 vs 35 ± 8%; P = 0.011) and LFS (5-year LFS: 9 ± 15 vs 34 ± 10%; P = 0.04) and a trend towards higher CIR (P = 0.1) (Figures 2a–c). In the multivariate analyses, miR-3151 expression retained its prognostic value in the UNFAVmol subgroup for OS (OR: 2.72; 95% CI: 1.53–4.84; P = 0.001) and LFS (OR: 2.28; 95% CI: 1.10–4.72; P = 0.026) (Table 2).

Despite the small size of the high miR-3151 expressers in the FAIVmol subgroup (n = 6 out of 50), high levels of miR-3151 were also associated with shorter OS (5-year OS: 33 ± 38 vs 70 ± 12%; P = 0.046) (Figure 2d), with a nonsignificant trend for LFS (P = 0.1). Given the different expression level according to NPM1 mutation, prognostic impact was also analyzed separately in NPM1mut and NPM1wt cohorts. Thus, among NPM1wt AML patients, patients with higher miR-3151 levels showed a worse outcome, with a shorter OS (5-years OS: 5 ± 10 vs 40 ± 10%; P = 0.012) and LFS (5-years LFS: 7 ± 14 vs 36 ± 11%; P = 0.005) and a higher CIR (5-years CIR: 77 ± 20 vs 52 ± 12%; P = 0.033) (Supplementary Figures 1a–c).

The combination of miR-3151 and BAALC expression provides additional independent prognostic value in IR-AML

In order to analyze the potential contribution to prognosis of the combined expression of miR-3151 and the expression of its host gene BAALC, we first studied the prognostic impact of BAALC expression in this cohort. The optimal cut-off point was determined using MaxStat (Figure 3a). Patients with higher BAALC expression had poorer OS than those with lower expression levels (5-year OS: 31 ± 10 vs 50 ± 10%; P = 0.01) (Figure 3b), poorer LFS (5-year LFS: 32 ± 10 vs 54 ± 10%; P = 0.004) and higher CIR (5-year CIR: 56 ± 12 vs 32 ± 12; P = 0.0019).

Given the prognostic value shown by the expression level of miR-3151 and BAALC as individual markers in the present study and

Abbreviations: CI, confidence interval; OR, odds ratio; UNFAVmol, unfavorable molecular group. Age was analyzed with 10-year intervals and white blood cell count at diagnosis using 50x10⁹/l increments.
the prognostic value of both factors in combination demonstrated in a previous study performed by the CALGB study in older patients,30 we then analyzed the prognostic impact of the combination in our cohort of younger patients. High miR-3151 and high BAALC expression were defined as high-risk factors. Patients were classified into three groups according to the number of high-risk factors: low-risk group, 0 factors; intermediate-risk group, 1 factor; and high-risk group, 2 factors. For the low-, intermediate- and high-risk groups, 5-year OS was $56 \pm 10\%$, $33 \pm 10\%$, and $7 \pm 14\%$, respectively ($P = 0.003$) (Figure 3c), 5-year LFS was $54 \pm 12\%$, $37 \pm 12\%$, and $1 \pm 18\%$, respectively ($P = 0.002$) (Figure 3d), and 5-year CIR was $33 \pm 11\%$, $46 \pm 13\%$, and $90 \pm 37\%$, respectively ($P < 0.001$) (Figure 3e). The multivariate analyses confirmed the combination as an independent prognostic factor in OS (OR: 1.65; 95% CI: 1.14–2.39; $P = 0.007$), LFS (OR: 2.05; 95% CI: 1.26–3.32; $P = 0.004$), and CIR (OR: 1.99; 95% CI: 1.19–3.39; $P = 0.008$), after adjustment for other well-recognized molecular and clinical prognostic markers (Supplementary Table 1).

Correlation of miR-3151 with miRNA expression
We had previously performed a comprehensive miRNA expression analysis in 78 patients of this cohort35 using TaqMan Array Human MicroRNA Set Cards v2.0 (AB). Remarkably, high expression of miR-3151 was associated with a miRNA signature in the group of patients with available miRNA profile, using BRB program from R. This signature comprised the overexpression of miR-501-5p ($P < 0.001$), and downregulation of miR-590 ($P < 0.001$), miR-135a ($P < 0.001$), miR-100* ($P = 0.01$), miR-186* ($P = 0.01$) and let-7a* ($P = 0.01$) (Figure 4).

DISCUSSION
miRNAs are involved in diverse essential functional pathways both in normal and neoplastic cells,31–33 and the expression of certain miRNAs in CN-AML or IR-AML has been shown to have prognostic relevance that can add useful information to molecular stratification based on the analysis of NPM1, FLT3-ITD and CEBPA.
miR-3151 is a prognostic marker in IR-AML

Figure 3. miR-3151 and BAALC expression and outcome in younger IR-AML patients. (a) The optimal cut-off level for BAALC expression as identified by the MaxStat package. (b) Overall survival according to BAALC expression levels. (c) Overall survival according to the combination of miR-3151 and BAALC expression levels. (d) Leukemia-free survival according to the combination of miR-3151 and BAALC expression levels. (e) Cumulative incidence of relapse according to the combination of miR-3151 and BAALC expression levels.
outcome difference between both IR-AML cytogenetic subgroups

cytogenetic abnormalities beyond CN-AML, given the absence of
younger IR-AML patients.

prompted us to analyze its expression and prognostic effect in

its prognostic impact observed in an elderly AML cohort,

younger cohort might provide relevant clinical signifi

ance, by identification of a subgroup of IR-AML patients with a worse
outcome who can be candidates to alloHSCT in an early phase. Moreover, miR-3151 can be particularly useful among patients without NPM1 mutations, who lack an universal molecular marker for minimal residual disease monitoring as NPM1mut AML patients.

IR-AML, the largest AML cytogenetic subgroup, comprises patients with highly diverse prognosis, for whom the optimal therapeutic strategies still largely unclear in several subgroups. Currently prognostic stratification in these patients is based on the analysis of a limited number of molecular markers, mainly NPM1, FLT3-ITD and CEBPA, as recognized in the European LeukemiaNet risk classification. Nonetheless the complex interaction of these markers with many other gene mutations that can modify the final prognostic impact, or the effect of intrinsic mutational character-

istics, such as, allelic burden or mutation site on protein function and prognosis, make molecular risk stratification a highly complex process. In this context, the investigation of alternative biological AML features, such as gene or non-coding RNA expression, might provide relevant additional information on mechanisms of chemoresistance which might summarize the resultant effect of diverse combination of gene mutations. Few studies have identified several miRNA with prognostic value, including a 4-miRNA signature described by our group in the intermediate-risk AML cohort. miR-3151, described more recently, was not included in this previous study; its particular location, within a BAALC intron, a well-known AML prognostic factor, and its prognostic impact observed in an elderly AML cohort, prompted us to analyze its expression and prognostic effect in younger IR-AML patients.

For this prognostic evaluation, we included different IR-AML cytogenetic abnormalities beyond CN-AML, given the absence of outcome difference between both IR-AML cytogenetic subgroups (that is, normal an abnormal IR-AML karyotypes). Furthermore, IR-AML usually comprise all cytogenetic aberrations not allocated to good and poor-risk subgroups, and it is usually considered as the same risk category for post-remission therapy decision, which in younger patients includes the decision to perform an alloHSCT in CR1. Remarkably, miR-3151 expression analysis revealed prognostic value, with a detrimental effect among patients with higher levels. Of note, miR-3151 was especially informative in the subset of patients with an unfavorable genotype according to NPM1/ FLT3-ITD/CEBPA configuration and in the group of patients lacking NPM1 mutations, identifying a subgroup with a particular poor outcome. Availability of an additional prognostic tool in the poorest prognosis subsets could be of evident clinical interest in the subgroup of IR-AML patients not harboring a favorable genotype (such as those defined in the European LeukemiaNet favorable category). Moreover, prognostic value of miR-3151 was independent of other well-characterized prognostic factors such as age, white blood cell count and gene mutations, and, interestingly, retained its prognostic value when our previously 4-miRNA score was included in the analysis (Supplementary Table 2). Prognostic impact of miR-3151 was even enriched with the simultaneous determination of BAALC which allowed us to build a simple score based on these two factors.

Importantly, although several miRNAs have been identified as prognostic markers in AML, their prognostic value has rarely been confirmed by subsequent studies by different cooperative groups. Here we have built on previous findings by CALGB showing the importance of miR-3151 and BAALC expression in older CN-AML patients and have validated their findings in younger IR-AML patients. In a further step, we have also identified a miRNA signature associated with higher expression of miR-3151, comprising a distinctive expression level of several miRNAs, such as let-7a*, miR-100*, miR-186*, miR-135a, miR-501-5p and miR-590.

We have shown in the present study that high expression of miR-3151—both alone and in combination with high BAALC expression—is an independent prognostic factor associated with poor outcome in younger IR-AML patients. These results confirmed for the first time the prognostic value of this miRNA previously observed in an older IR-AML cohort, and suggest that determination of its expression levels might improve risk
stratification and post-remission treatment evaluation of younger IR-AML.

CONFLICT OF INTEREST
The authors declare no conflict of interest.
