An investigation of the two-dimensional Widom-Rowlinson lattice gas under an applied drive uncovered a remarkable non-equilibrium steady state in which uniform stripes (reminiscent of an equilibrium lamellar phase) form perpendicular to the drive direction [R. Dickman and R. K. P. Zia, Phys. Rev. E 97, 062126 (2018)]. Here we study this model at low particle densities in two and three dimensions, where we find a disordered phase with a characteristic length scale (a “microemulsion”) along the drive direction. We develop a continuum theory of this disordered phase to derive a coarse-grained field-theoretic action for the non-equilibrium dynamics. The action has the form of two coupled driven diffusive systems with different characteristic velocities, generated by an interplay between the particle repulsion and the drive. We then show how fluctuation corrections in the field theory may generate the characteristic features of the microemulsion phase, including a peak in the static structure factor corresponding to the characteristic length scale. This work lays the foundation for understanding the stripe phenomenon more generally.

I. INTRODUCTION AND BACKGROUND

Modulated or spatially-patterned phases abound in and out of equilibrium: Block copolymers, magnetic thin films, type-I superconductor films in applied magnetic fields, cholesteric liquid crystals [1], and lipid mixtures may all exhibit thermodynamically stable, patterned equilibrium phases [2]. On the other hand, driven granular systems [3], Rayleigh-Bénard convection rolls [1], and other out-of-equilibrium systems exhibit spatially-modulated, dynamical steady states [4], as well. In these systems, when an equilibrium, free-energy-based treatment is appropriate, one may often define a coarse-grained scalar order parameter ψ(r) which, in the ordered phase, has some spatial modulation with a characteristic wavenumber $q^* = 2\pi/\lambda^*$ describing the pattern size $\lambda^*$. A common ordered phase consists of stripes (or slabs, in 3D) with $\psi(r) \propto \cos(q^*x)$ for describing a structure periodic in some x direction.

In the disordered phase, with $\langle \psi \rangle = 0$ on average, the characteristic pattern size may also show up as a peak in the static structure factor at $q^*$. Such a peak is observed in scattering intensity distributions of oil-and-water mixtures, which may be treated with a phenomenological free energy of the kind considered here [5]. We therefore refer to the “structured” disordered phase as a microemulsion. Such a phase is characterized by clustering at a particular length scale $\lambda^*$, but without any long-range, ordered patterning. Such phases may contain droplets or have a bicontinuous, disordered structure. The presence of a characteristic $q^* > 0$ in the disordered phase also strongly modifies the phase behavior, as the thermal fluctuations of the order parameter $\psi$ occur predominantly in a non-zero momentum “shell” $|\mathbf{q}| = q^*$.

For the systems admitting an equilibrium treatment, the origin of the special scale $q^*$ may come from some competing interactions, such as a coupling of a lipid membrane composition to the membrane curvature [7] or be set by particular boundary conditions [4]. Once the scale $q^*$ has been identified, such systems near the pattern-formation transition are described by a phenomenological, coarse-grained free energy, first analyzed by Brazovskii and coworkers [8, 9]. In this work, we explore a system where the scale $q^*$ develops unexpectedly and no coarse-grained free energy is a priori available due to the explicitly out-of-equilibrium state of the system: The patterns develop in a phase-separating binary mixture of particles with purely repulsive interactions under an applied drive [10]. We will show that the origin of $q^*$ is subtle in this case, and results from an interplay between the repulsive interactions and the applied drive.

Strongly-driven physical systems exhibit a range of out-of-equilibrium, pattern-forming phenomena. For example, laning or striped behavior is known to occur in a wide range of systems, including vibrated granular mixtures with varying friction coefficients [11], driven polymer blends [12], and binary plasmas [13]. In most of these systems, the stripes form parallel to the drive di-

FIG. 1. Snapshots of steady states of the driven Widom-Rowlinson lattice gas (DWRLG) for a $L \times L$ system with $L = 400$ with equal mixtures of blue and orange particles. At high densities ($\bar{\rho} = 0.7$), the mixture phase separates either completely without a drive ($\delta = 0$) or into uniform stripes with a drive ($\delta = 0.5$). At lower densities ($\bar{\rho} = 0.5$), the particles remain mixed. In the presence of a drive, in the direction given by the red arrow, the disordered phase has a characteristic length scale as can be observed from the static structure factors $S_\psi(q)$ (the insets). Note that the $\delta = 0$ case has a single peak at the origin, while the $\delta = 0.5$ case has two maxima away from the origin along the drive direction.

FIG. 2. Snapshots of steady states of the DWRLG for a $L \times L \times L$ system with $L = 100$ with equal mixtures of blue and orange particles. At high densities ($\bar{\rho} = 0.5$), the binary mixture phase separates either completely without a drive ($\delta = 0$) or into slabs with a drive ($\delta = 0.5$). The drive direction, $\hat{x}$, is shown with a red arrow. At lower densities ($\bar{\rho} = 0.33$), the particles remain mixed. The static structure factors $S_\psi(q)$ for the disordered phases are shown as a function of $q = (q_\parallel, q_\perp)$, where we average over the two directions perpendicular to the drive. Note the two maxima in the drive direction (inset on bottom right).

Granular [36] and colloidal systems [37] under an oscillatory drive can also form jammed clusters with the stripes running perpendicular to the drive direction. The dynamic instabilities observed in the sheared granular systems are reminiscent of the phenomenon described here [38, 39]. However, the stripes of granular particles typically coarsen over time, with the cluster sizes eventually approaching the system size. Conversely, our model shows stable structures at a characteristic scale $\lambda^*$ at the longest time scales available in our simulations ($10^8$ Monte-Carlo steps, as discussed in the next section). Moreover, fully phase-separated states are observed to breakup until the clusters reach the characteristic size.

We consider the Widom-Rowlinson lattice gas with two species $[40]$, $A$ and $B$. The particles hop on a square or a simple cubic lattice, subjected to excluded-volume interactions. $A$ and $B$ particles cannot occupy nearest-neighbor sites, modelling a repulsive interaction between species $[4]$. The original, off-lattice version of this model with purely repulsive interactions may be

---

1 Whether driven or not, this system on a one-dimensional pe-
mapped to a single-component gas with attractive interactions and exhibiting a vapor-liquid transition \[47\]. In the two-species case, the analog of the vapor-liquid transition is a phase separation of the two species when their density \( \bar{\rho} \) (for equal proportions of the two species, \( \rho_A = \rho_B = \bar{\rho}/2 \)) is larger than a critical value \( \bar{\rho}^* \). At low densities \( \bar{\rho} \), the particles remain mixed on average. These ordered and disordered equilibrium phases are shown in the left panels of Figs. 1 and 2 for two- and three-dimensional systems, respectively. A key quantity that characterizes the ordering process (into periodic structures) is the difference between the coarse-grained (local) particle densities \( \psi(r,t) = \rho_A(r,t) - \rho_B(r,t) \). We will study what happens to this density when the particles are “driven” uniformly, i.e., particle-hole exchanges in one direction are biased, as if the particles are placed in a uniform gravitational field. The effects of the drive are dramatic, as shown in the right panels of Figs. [1, 2]. At low \( \bar{\rho} \), we find a disordered phase with a characteristic peak in the static structure factor \( S_\psi(q) \) (associated with the “charge field” \( \psi \)) along the drive direction (a “microemulsion”) and at high \( \bar{\rho} \) we find an ordered phase of stripes (or slabs in 3D), reminiscent of a smectic liquid crystal.

To understand the structure of these phases, we begin with a free energy for the equilibrium case with no drive. It has been shown that without the drive, the lattice gas phase separation is in the Ising universality class \[10\] (with the underlying system being a diluted Ising one). As the number of particles remains fixed, we expect the charge field \( \psi \) to behave as a conserved “magnetization,” with the following coarse-grained free energy \( \mathcal{F} \):

\[
\mathcal{F} = \int \! dr \, \! dr' \psi(r') G^{-1}(r-r') \psi(r) + \int \! dr \, \! \Delta V_I[\psi(r)],
\]

where \( G(r-r') \) is the Green’s function and \( \Delta V_I[\psi(r)] = \psi^2 \) and the (Fourier-transformed, inverse) Green’s function is the usual \( G^{-1}(q) = \tau + C q^2 \), with constants \( C > 0 \) and \( \tau \). Ignoring fluctuations, \( \tau \propto \bar{\rho}^* - \bar{\rho} \) is our control parameter with \( \tau > 0 \) for the disordered phase (bottom left of Figs. [1, 2]) and \( \tau \leq 0 \) for the phase separated phase (top left of Figs. [1, 2]). The particle conservation law would show up in the equation of motion for \( \psi \), which must be of the conserved (model B \[48\]) form given by

\[
\partial_t \psi(r,t) = D \nabla^2 \psi(r,t) + \xi(r,t),
\]

with \( \xi(r,t) \) a Gaussian, conserved noise with correlations satisfying the fluctuation-dissipation theorem:

\[
\langle \xi(r,t)\xi'(r',t') \rangle = -2k_B T D \nabla^2 \delta(r-r')\delta(t-t'),
\]

with \( D \) a diffusion constant, \( k_B \) the Boltzmann constant, and \( T \) the temperature. The mobility \( D \) and temperature \( T \) depend on the specific microscopic lattice rules, as well as the coarse-graining procedure. The important point to make here is that, without a drive, there is nothing to set the preferred scale \( q^* \). The disordered phase (\( \tau > 0 \)) has a structure factor (i.e., the Fourier-transform of the equal-time two point correlation)

\[
S_\psi(q) \propto (\tau + C q^2)^{-1},
\]

peaked at the origin \( q = |q| = 0 \). We verify this in our simulations in the bottom left panels of Figs. [1, 2] for two and three dimensions, respectively. In the ordered phase \( \tau < 0 \), the binary mixture eventually fully phase separates. We can also see this in our simulations in the top left panels of Figs. [1, 2].

In the presence of a drive, novel features emerge. In particular, our model exhibits behavior reminiscent of systems with modulated phases in equilibrium, with some important differences. A modulated phase at equilibrium would have \( S_\psi(q) \) with a maximum at a nonzero wavenumber: \( S_\psi(q) \propto \left[ \tau + \kappa_\parallel (|q| - q^*)^2 \right]^{-1}, \) with \( q^* = 2\pi/\lambda^* \) and \( \lambda^* \) the characteristic wavelength of the spatial modulation. In a scattering experiment, we would expect a large contribution at this wavenumber for any direction \( \mathbf{q} \). Conversely, in our model, the applied drive breaks the rotational symmetry of our system and the static structure factor \( S_\psi(q) \) only has peaks along the drive direction, with \( S_\psi(q) \propto \left[ \tau + \kappa_\perp |q_\perp|^2 \right]^{-1}, \) where \( q_\parallel = \mathbf{q} \cdot \mathbf{x}_\parallel \) is the component of the wavevector parallel to \( \mathbf{x}_\parallel \) and \( q_\perp \) the component perpendicular to the drive direction \( \mathbf{x}_\parallel \). Here we use simulations and a coarse-grained field-theoretic approach to see how such a peculiar “microemulsion” phase may develop.

Another important limit worth mentioning is the out-of-equilibrium, low particle density \( \rho \) limit at non-zero drive. Here, we expect the inter-species repulsive interactions to be negligible and the lattice gas should reduce to the low density phase of a non-interacting driven diffusive system (DDS) \[49, 50\]. The excluded volume condition, however, should still be relevant and appears as an interaction “along the drive” (see the term proportional to \( g \) below). The local particle density \( \rho \equiv \rho_A(r,t) + \rho_B(r,t) \) would obey, in the frame moving with the mean particle velocity induced by the drive \( \delta \), the Langevin equation

\[
\partial_t \rho = D(\partial^2 \rho + \nabla^2 \rho) + g \partial_t |\rho|^2 + \xi_\rho(r,t),
\]

where \( \xi_\rho(r,t) \) is a conserved noise satisfying

\[
\langle \xi_\rho(r,t)\xi_\rho(r',t') \rangle = -2D(\partial^2 \rho + \nabla^2 \rho)\delta(r-r')\delta(t-t'),
\]

and \( c, \tilde{c} \) are coefficients reflecting the anisotropy in the
diffusion and noise, respectively. Detailed balance is violated and a renormalization group analysis leads to anomalous diffusion (only in the direction of the drive) for \( d \leq 2 \) [49, 50]. We shall see that Eq. (3) represents the coarse-grained dynamics of our model in the important limiting case of low particle density and no repulsive interaction between particle species. As in DDS, Eq. (3) embodies a discontinuity singularity to anomalous diffusion (only in the direction of the drive) for \( d \leq 2 \) [25, 26, 51]. Moreover, it is known that single-species systems with attractive interactions do not form modulated phases, either. If any spatial structures emerge (e.g., stripes of high and low densities), they are invariably aligned parallel to the drive (see, e.g., Ref. [51]). Note, however, that it has no characteristic peak of the kind shown in Figs. 1a [2] (see insets in bottom right panels) [52, 53]. Moreover, it is known that single-species systems with attractive interactions do not form modulated phases, either. If any spatial structures emerge (e.g., stripes of high and low densities), they are invariably aligned parallel to the drive [25, 26, 51].

Thus, the behavior analyzed in the two-species model presented here is remarkable and unintuitive, especially in light of the limiting, well-studied cases described above.

The remainder of this paper is organized as follows: In the next section we define the model. Then, in Sec. III we present simulation results on the disordered phase, including static structure factor calculations and the characteristic wavevector \( q_0^d \) along the drive direction as a function of the drive \( \delta \). In Sec. IV, we derive a field theory corresponding to the lattice gas rules and show that, at the mean-field (Gaussian) level, it predicts some features of the disordered phase, yet missing the most prominent properties. Fluctuation corrections are discussed in Sec. V, and we show that a simple perturbative approach is able to capture, if only qualitatively, the essential behavior exhibited by our driven lattice gas. We conclude in Sec. VI and offer some directions for future investigation.

II. MODEL

We consider a lattice gas with two particle species, \( A \) (orange) and \( B \) (blue), that occupy sites \( x = \ell(i,j) \) on a square lattice or \( x = \ell(i,j,k) \) on a cubic lattice (with \( i,j,k \) integers), with \( \ell \) the lattice spacing and \( L \) the length of the lattice. The space of allowed configurations is defined by the restrictions that (1) all particles occupy distinct sites, and (2) \( A-B \) nearest-neighbor pairs are prohibited, as shown in Fig. 3. We impose periodic boundary conditions in all directions. It is convenient to introduce spin variables \( \sigma_x = 0, \pm 1 \) at each site, defined so:

\[
\sigma_x = \begin{cases} 
1, & x \text{ is occupied by } A \\
-1, & x \text{ is occupied by } B \\
0, & x \text{ is empty.}
\end{cases}
\]  

The numbers of \( A \) particles \( N_A \), and of \( B \) particles \( N_B \) remain fixed, as do the average densities, \( \bar{\rho}_{A,B} = N_{A,B}/L^d \).

The hopping rules are those in Ref. [10] with \( \alpha = 1/4 \): At each time step, we pick a random particle at location \( x \) and move it to a nearest-neighbor (NN) or next-nearest-neighbor (NNN) site \( x + \Delta x \) with the following probabilities:

\[
\omega_{x\rightarrow x+\Delta x} = \frac{1}{N_n} \begin{cases} 
1 + \delta, & \Delta x \cdot \bar{x} > 0 \\
1 - \delta, & \Delta x \cdot \bar{x} < 0, \\
1, & \Delta x \cdot \bar{x} = 0
\end{cases}
\]

where \( 0 \leq \delta \leq 1 \) is the drive strength, \( \bar{x}_q \) is the drive direction, and \( N_n \) is the number of NN and NNN sites. \( (N_n = 8 \text{ and } 18 \text{ the square and simple cubic lattices, respectively.}) \) The particle displacement is accepted subject to the restrictions mentioned above. Note that the rules are completely symmetric for the two species, so there is an “Ising-like” symmetry \( \sigma_x \rightarrow -\sigma_x \) (so long as we keep the number of particles of each type the same, with \( N_A = N_B \)). After each such update, time advances by \( 1/N \), where \( N = N_A + N_B \) is the total number of particles. We define one Monte-Carlo step (MCS) as having completed \( N \) such attempts and will label MCS by \( n = 1, 2, ..., N_{\text{MC}} \). In our simulations, the runs involve typically \( N_{\text{MC}} \) up to \( 5 \times 10^7 \), with the longest runs going up to \( 10^8 \) MCS. Measurements are taken typically after discarding the initial \( 4 \times 10^6 \) MCS so that the system has arrived at a (reasonable) stationary state.

In equilibrium (no drive, \( \delta = 0 \)), the model exhibits a phase transition at a critical density \( \bar{\rho}^c = 0.617(1) \) and \( \bar{\rho}^c = 0.3543(1) \) in two and three dimensions, respectively [40]. The transition is in the Ising universality class and describes the usual demixing transition of a binary mixture at sufficiently high densities. Examples of the disordered and ordered phases are shown in the left columns of Figs. 1 and 2. One may track the transition via the structure factor associated with the “charge”
order parameter field $\psi(r)$:

$$S_\psi(q) = \frac{1}{L^d} \sum_{x,r} \langle \sigma_x \sigma_{x+r} \rangle e^{i q \cdot r} = \frac{\langle |\sigma(q)|^2 \rangle}{L^d}, \quad (6)$$

where $\sigma(q)$ is the Fourier-transformed particle configuration $\sigma_x$ and $L^d$ the volume of the square ($d = 2$) or cubic ($d = 3$) lattice. For a phase with a characteristic length, we expect to find peaks in $S_\psi(q)$. We will analyze the formation of this “microemulsion peak” using simulation and a field-theoretic approach.

### III. MICROEMULSIONS IN SIMULATIONS

We begin with simulation results that give the basic phenomenology of this system. We have simulated both two- and three-dimensional systems, but since it is easier to go to larger system sizes in two dimensions, this will be our primary focus. We will also primarily focus on the behavior of the system below the transition point ($\bar{\rho} < \bar{\rho}^*$) where we find a disordered “microemulsion” phase. As discussed in the previous section, although we do not have the distinct stripe order at low densities, the small fluctuating domains of particles in the system are characterized by a distinct length scale along the drive direction. This manifests as a peak in the structure factor $S_\psi(q)$ at $q = (q^*_\parallel, 0)$. As one approaches the critical density $\bar{\rho} \to \bar{\rho}^*$, this peak value begins to diverge with the system size, as we develop the uniform stripe order seen in the top right panels of Figs. 12. For $\bar{\rho} < \bar{\rho}^*$, the position of the peak $q^*_\parallel$ in the drive direction grows linearly with the drive $\delta$ in both two and three dimensions, as shown in Fig. 4. This is also reflected in the coarser texture of the microphase pattern for smaller $\delta$, evident in the configuration snapshots.

At small $q^*_\parallel$, we have verified that the kinked form is not a finite-size effect by checking that the form does not change as we vary the lattice size: $q^*_\parallel \propto \delta$. The error bars indicate $2\pi/L$ which sets the k-space resolution ($L = 400$ for 2D and $L = 100$ for 3D). This linear variation of $q^*_\parallel$ with $\delta$ in the disordered phase is consistent with our field-theoretic analysis. Typical system snapshots are shown for the square lattice on the right panels for $\bar{\rho} = 0.5$ and the indicated drive values $\delta$.

In the previous work on this model [10], the conjectured simplest form of the static structure factor $S_\psi \equiv S_\psi(q)$, consistent with a dominant contribution at a nonzero $q = (q^*_\parallel, 0)$, reads

$$S_\psi[q = (q^*_\parallel, q^*_\perp)] = \frac{\nu_\parallel q^2_\parallel + \nu_\perp |q^*_\perp|^2}{\tau_\parallel q^2_\parallel + \tau_\perp |q^*_\perp|^2 + q^2_\perp (|q^*_\parallel|^2 - q^2_\parallel)^2 + \gamma_\parallel q^2_\parallel |q^*_\perp|^4 + \gamma_\perp |q^*_\perp|^4 + \ldots} \quad (7)$$

with ellipses indicating corrections in higher powers of the momentum $q$. The new interesting feature here is the cubic term, $-2q^2_\parallel |q^*_\parallel|^3$, in the denominator, which is responsible for the peak in the structure factor. The cubic term is unexpected from a mean field analysis and a naive continuum limit of the model, which yields only even powers of $q^*_\parallel$ and no drive-dependence in any of the terms. The cubic term also yields a linear kink in the static structure factor near the origin along the drive direction, as evidenced in Figs. 5 and 6, where we fit the conjectured form in Eq. (7) to simulation data for $q^*_\perp = 0$. Note how well the form reproduces the features at small $q^*_\parallel$. In two dimensions, we have verified that the kinked form is not a finite-size effect by checking that the form does not change as we vary the lattice size: $L = 100, 200, 400$. Also, as far as can be estimated from simulations, the peak exists for any $\delta > 0$. Our objective, then, is to explore how such a structure factor form may come about from a field-theoretic analysis of this model.

The static structure factors in two and three dimensions as a function of $q$, both parallel and perpendicular to the drive, are shown in Fig. 5 as measured from simulations. It is worth noting that the static structure factors exhibit a characteristically jump discontinuity near the origin, captured by our conjectured form in Eq. (7) by setting $\nu_\parallel/\tau_\parallel \neq \nu_\perp/\tau_\perp$. We also see that the structure factors monotonically decrease along the direction $q^*_\perp$ perpendicular to the drive for $q^*_\parallel = 0$. Along this direction, the structure factor is well-approximated by a simple Ornstein-Zernike form, corresponding to the $q^*_\parallel = 0$ case in Eq. (7).

---

2 Also, the two-point correlation function must obey an underlying parity symmetry, which constrains it to be symmetric under $q^*_\perp \to -q^*_\perp$. The drive breaks this symmetry, but this feature can only appear at the level of three-point (or larger) correlation functions.
Before moving on, let us consider the static structure factor $S_\rho(q)$ for the density field $\rho \equiv \rho_A + \rho_B$ in two dimensions. This also has an interesting structure when the drive $\delta$ is applied, as can be seen in Fig. 7. Note how there is a kinked structure near $q_\parallel = 0$ that is of the opposite sign as $S_\psi(q)$ in Fig. 6. As shown in Fig. 7, the kinked increase at $q_\parallel = 0$ grows with increasing drive $\delta$ but starts to decrease for the largest drives. We will show that the kink near the origin likely comes from the fluctuation corrections in the field-theoretic description, just as for the charge fields. We should remark that $S_\rho(q)$ does not appear to exhibit any discernible signatures of the characteristic wavevector $q^*_\parallel$. On closer examination, however, we can detect a shoulder in the $\delta = 0.5$ data, at roughly $2q^*_\parallel$. We suspect that, especially for the small $\delta$ systems, the enhancement manifest in $S_\rho$ is mostly shrouded by the much larger effect near $q_\parallel = 0$ here. These properties are only true at small $\bar{\rho}$. In the high density, ordered phase (with $\bar{\rho} > \bar{\rho}^*$), $S_\rho(q)$ displays a peak at $q = (q_\parallel = 2q^*_\parallel, q_\perp = 0)$, because high density stripes of $A$ and $B$ particles alternate, separated by low density regions (of many vacancies) [10]. Of course, the static structure factors $S_{\psi,\rho}(q)$ display only part of the interesting behavior we observe. The dynamic structure factors $S_{\psi,\rho}(r,n)$ for the charge and density fields are also important, as they directly capture not only the diffusive properties of the particles, but also the advection. In particular, we may measure the unequal time correlations given by

$$S_\psi(r,n) = \frac{1}{L^d} \sum_{x,t} (\sigma_x(t)\sigma_{x+r}(t+n))$$

$$S_\rho(r,n) = \frac{1}{L^d} \sum_{x,t} ([|\sigma_x(t)||\sigma_{x+r}(t+n)| - \bar{\rho}^2]$$

with $\sigma_x(t)$ the spin configuration at time step $t$ and lat-

FIG. 7. Static structure factor $S_{\rho}(q)$ [with $q = (q_{\parallel}, q_{\perp})$] of the density field $\rho = \rho_A + \rho_B$, as a function of $q_{\parallel}$, with $q_{\perp} = 0$, measured in simulations for drives $\delta$ as indicated. $S_{\rho}$ is calculated using a two-dimensional system with $L^2 = 400^2$ lattice sites at an average particle density of $\bar{\rho} = 0.5$ (equal fractions of $A$ and $B$ particles). The inset, which has the same axes as the main plot, shows a detail of the small-$q$ region. $S_{\rho}$ has a cusped, sharp increase near $q_{\parallel} = 0$, consistent with a logarithmic divergence. Unlike in the case of the charge structure factors $S_{\psi}$ shown in Fig. 8(a), we do not find a peak here.

Note that the charge and density dynamic structure factors have very different behaviors: The peaks of the charge field structure factor $S_{\psi}$ (lower panel) propagates more rapidly and spreads more slowly than the density field structure factor, $S_{\rho}$ (upper panel). Both have Gaussian shapes. These properties can be understood within a field-theoretic framework.

FIG. 8. Dynamic (real-space) structure factors [defined in Eqs. (9)] calculated from a two-dimensional simulation with equal fractions of $A$ and $B$ particles with $\bar{\rho} = 0.1$ and $\delta = 0.3$ (system size $L = 50$). The factors are evaluated along the drive direction $r = (x_{\parallel}, 0)$. The charge field structure factor $S_{\psi}(r, n)$ (lower panel) propagates more rapidly and spreads more slowly than the density field structure factor, $S_{\rho}(r, n)$ (upper panel). Both have Gaussian shapes. These properties can be understood within a field-theoretic framework.

IV. COARSE-GRAINED FIELD-THEORETIC MODEL

To understand how these unusual properties arise from being driven, even if only qualitatively, we will attempt an approach based on coarse-graining our discrete lattice system to a continuum field-theory. Starting with a set of stochastic update rules, such as those described by Eq. (5), it is straightforward to derive a master equation for the evolution of the probability $P(\{\sigma_x\}, t)$ of observing a particular lattice configuration $\{\sigma_x\}$ at time $t$. From here, there are standard procedures for converting that description into one based on a Langevin equation for coarse-grained density fields $\rho_{A,B}(x, t)$. A common approach employs the Martin-Siggia-Rose-Janssen-de Dominicis (MSRJD) formalism which translates these equations into a field-theoretic, “dynamical action” $\mathcal{J}$ involving both the $\rho_{A,B}$’s and corresponding “response fields” $\tilde{\rho}_{A,B}(x, t)$. Following the general procedure for particle hopping models [57], the dynamical action reads

$$\mathcal{J}[\rho_{A,B}, \tilde{\rho}_{A,B}] = \sum_{\alpha = A, B} \int dt \left\{ \sum_x \tilde{\rho}_\alpha \partial_t \rho_\alpha + \sum_{(xy)} W_{x,y}^\alpha \left[ 1 - e^{\tilde{\rho}_\alpha(x) - \tilde{\rho}_\alpha(y)} \right] \right\},$$

where $W_{x,y}^\alpha$ are the hopping rates from site $x$ to $y$ for particles of type $\alpha = A, B$ [which can be gleaned from the $\omega$’s in Eq. (5)]. These $W$’s encode both the hopping and the exclusion rules and must vanish for any prohibited hops (see Fig. 3). We sum over all pairs of NN and NNN sites $\sigma_{xy}$. From here, the average over many stochastic realizations of the particle system may be computed for any functional of the densities $\mathcal{O}(\{\rho_{A,B}\})$. 

Euler-Lagrange equations associated with extremizing with \("observables\) using the action \(J\) with an appropriate interpretation of the response fields \(\rho_{A,B}\) lead us to Langevin equations for the densities \(\rho_{A,B}(x,t)\). As these are more easily grasped intuitively, we will present the field theoretic formulation in such terms [see Eqs. (12) below].

A second method (Doi-Peliti [55, 59]) of deriving a coarse-grained description of the dynamics and the dynamical action \(J\) involves reformulating the master equation for \(P(\{\sigma_x\}, t)\) using a Fock space where the probability distribution \(P\) is encoded in a multi-particle state. Then, using a coherent state path integral representation of the master equation, one is able to derive a dynamical action of the same form as Eq. (10). In principle, these two methods yield equivalent field theories [51], but the mapping is non-trivial. Also, a special difficulty in our case is that both the excluded volume constraint and the \(A,B\) particle next-nearest neighbor exclusion rule are not easily incorporated. One possibility, introduced by van Wijland [60], is to apply the exclusion rules at the level of the master equation, which is exact but difficult to interpret when we coarse-grain. A review can be found in, e.g., Ref. [61]. This procedure is quite involved and some details are provided in Appendix A for the interested reader.

Encouragingly, after taking the continuum limit and expanding around small density fluctuations, both the Doi-Peliti and MSRJD methods yield the same structure for the field theory, with minor variations in the dependencies of the coupling constants on the microscopic parameters \(\tilde{\rho}_{A,B}\) and \(\delta\). In the following we use results from the Doi-Peliti approach using van Wijland’s method for excluded volume interactions.

In the paradigm of this coarse-grained continuum description, we assume the density fields \(\rho\) and their corresponding response fields \(\rho_\alpha\) are slowly varying in space and time \((r,t)\). To construct a perturbation theory and compare to our simulation results, we transform to more convenient fields (i.e., ones which diagonalize the quadratic part in \(J\): the total density \(\rho = \rho_A + \rho_B\) and the “charge” order parameter \(\psi = \rho_A - \rho_B\)). We have to expand the fields \(\rho\) and \(\psi\) around some uniform concentrations \(\bar{\rho}\) and \(\bar{\psi}\) which, along with the drive \(\delta\), are our control parameters in the simulations. With the replacements \(\rho = \bar{\rho} + \phi_+\) and \(\psi = \bar{\psi} + \phi_-\), we find that, to leading order in the fluctuations \(\phi_\pm\) and the averages, the Langevin equations read

\[
\begin{align*}
\partial_t \phi_+ &= D_+ \nabla^2 \phi_+ - v_+ \partial_t \phi_+ - u_+ \bar{\psi} \partial_t \phi_- + g_+ \frac{\partial}{\partial x} (\phi_+^2) - g_+ \frac{\partial}{\partial x} (\phi_-^2) + \xi_+, \\
\partial_t \phi_- &= D_- \nabla^2 \phi_- - v_- \partial_t \phi_- + u_- \bar{\psi} \partial_t \phi_+ + g_0 \partial_t (\phi_+ \phi_-) + \xi_-,
\end{align*}
\]

where the coefficients of all the terms carry appropriate units of space (the lattice spacing \(\ell\)) and time (MCS) which will be suppressed. With this understanding, we find (the leading constants and lowest-order corrections in powers of \(\bar{\rho}\) and \(\bar{\psi}\) for) the diffusion \(D_{\pm} \approx 3/8\) and the velocities \(v_{\pm} = \bar{v} \pm \bar{v}_d/2\) with average \(\bar{v} = (v_+ + v_-)/2 \approx \delta (3 - 22\bar{\rho})/4\) and the difference \(v_d = v_+ - v_- \approx -5\bar{\rho}\delta/2\). The other velocities, \(u_{\pm} \approx 7\delta/4\) and \(u_- \approx 3\delta/4\), do not appear in this study, as we focus on neutral systems \((\bar{\psi} = 0)\) only. While \(\nabla^2 = \nabla_x^2 + \nabla_t^2\) represents isotropic diffusion, there are DDS-like anisotropic, non-linear couplings \(g_- = \sqrt{2\delta}\), \(g_+ = 4\sqrt{\delta}\), and \(g_0 = 3\sqrt{2\delta}\) all proportional to the drive \(\delta\). As we shall see, these interaction terms will generate anisotropy in the diffusion terms. We also find conserved noises for both the charge and density, with correlations given by: \(\langle \xi_+ \xi_+ \rangle = -2N_+ \bar{\rho} \bar{\psi}^2 \delta (r - r') \delta (t - t')\) and \(\langle \xi_- \xi_- \rangle = -2N_- \bar{\rho} \bar{\psi}^2 \delta (r - r') \delta (t - t')\), with \(N_{\pm} \approx 3/8\). When \(\bar{\psi} \neq 0\), there are nonzero cross-correlations, \(\langle \xi_+ \xi_- \rangle = -2N_+ \bar{\rho} \bar{\psi}^2 \delta (r - r') \delta (t - t')\), with \(N_{+} \approx 3/8\).

While it is of course possible to obtain more detailed expressions for the coupling constants in terms of the microscopic control parameters \(\bar{\rho}, \bar{\psi}, \delta\), they are not needed for our objective of understanding the coarse-grained features of the dynamics at small particle density \(\bar{\rho}\).

Note that when either of the two species vanishes, so that \(\rho = \psi = \rho_{A,B}\), both equations in Eq. (12) reduce to the DDS Langevin equation in Eq. (3) with \(g = g_0 = g_+ = g_-\) as the derivative coupling. This is an important limiting case as we would expect our model to reduce to the single-species DDS when we remove the repulsive interactions between particle species. The other important case is \(\delta = 0\), where we would expect phase separation of the \(A\) and \(B\) particles at sufficiently high densities. In this case, Eq. (12) reduces to a pair of independent diffusion equations. To understand the system at higher particle densities, higher-order terms in the fields \(\phi_\pm\) need to be included. If we further assume the density fluctuations \(\phi_\pm\) relax faster than the charge \(\phi_-\) and integrate out the former, the effective equation for the latter reduces to an Ising system with conserved dynamics (model B). However, this is a crude approximation and a more careful analysis would involve accounting for both fields \(\phi_\pm\) and considering the action at high particle densities \(\bar{\rho}\). Such a line of pursuit is beyond the scope of this paper. Here we focus on the low-density phase, and defer a detailed analysis of phase separation to future work.

We now discuss the dynamic action associated with the Langevin equations, Eqs. (12). To compare with simulation results, we impose equal average densities \((\bar{\psi} = 0)\) and find that, up to cubic terms in the fields...
and leading order in spatial derivatives, the action reads

$$\mathcal{J} = \int \! dr \, dt \left\{ \sum_{a=\pm} \left[ \phi_a (\partial_t - D_a \nabla^2 + v_a \partial_{\parallel}) \phi_a + \tilde{\rho} N_a \phi_a \nabla^2 \phi_a \right] + g_0 \phi_{\parallel} \phi_+ \phi_+ + \frac{g_+}{2} \phi_+^2 \partial_{\parallel} \phi_+ + \frac{g_-}{2} \phi_-^2 \partial_{\parallel} \phi_-ight\}. \quad (13)$$

In the disordered phase, $\tilde{\rho} < \bar{\rho}^*$, the diffusion constants $D_\pm$ are both positive. A scaling analysis (taking $r \to |x| \bar{\rho}$) shows that the scaling dimension of the drive couplings $g_{0,\pm}$ is $1 - d/2$, so that the upper critical dimension is $d_c = 2$ for the $\tilde{\rho} < \bar{\rho}^*$ regime, as it is for the single-species DDS at low densities \[^{50}\]. We therefore conclude that higher-derivative coupling terms are irrelevant in the renormalization group sense.

Next, we set up a diagramatic expansion using the action of Eq. (13). There are two kinds of propagators generated by the quadratic terms in the fields $\phi_\pm$ and $\phi_\parallel$. In the Fourier domain, we have the (bare) correlation functions $\langle \phi_a(q,\omega) \phi_a^\dagger(q',\omega') \rangle \equiv C_{\pm}(q,\omega) \delta(q+q') \delta(\omega+\omega')$ and the response functions $\langle \phi_a(q,\omega) \phi_\parallel(q',\omega') \rangle \equiv G_{\pm}(q,\omega) \delta(q+q') \delta(\omega+\omega')$. Using dotted and solid lines for the density and charge fluctuations, respectively, we denote these by the following:

$$\begin{align*}
G_{\pm} &= \frac{1}{\omega - v_{\pm} q_{\parallel}} + D_{\pm} |q|^2, \\
C_{\pm} &= \frac{2 N_a \tilde{\rho} |q|^2}{\omega - v_{\pm} q_{\parallel}} + [D_{\pm} |q|^2]^2.
\end{align*} \quad (14)$$

Both the numerators for $C_{\pm}$ and the denominators for $G_{\pm}, C_{\pm}$ have corrections in higher powers of $|q|^2$, starting with $|q|^4$. In the disordered phase $\tilde{\rho} < \bar{\rho}^*$, the quartic momentum terms are irrelevant. We will be interested in finding fluctuation corrections that generate a peak in the structure factor, along with a possible kink near the origin, which cannot exist in a mean-field theory. The reason is simple: Any odd terms in $q_{\parallel}$ are always imaginary and give contributions to the velocity terms proportional to the drive $\tilde{\rho}$. Therefore, they are always removed by an appropriate choice of co-moving frame for the fields $\phi_\pm$. We can see this explicitly when we calculate the static structure factors $S_{\rho,\psi}(q)$ directly from the correlation functions $C_{\pm}$.

$$S_{\rho,\psi}(q) = \int_{-\infty}^{\infty} \! \frac{d\omega}{2\pi} \left[ \frac{2 f_N^{(\pm)}(q)}{\omega - f_N^{(\pm)}(q)} \right]^2 + \left[ \frac{f_D^{(\pm)}(q)}{f_D^{(\pm)}(q)} \right]^2$$

$$= \frac{f_N^{(\pm)}(q)}{|f_D^{(\pm)}(q)|} \quad (15)$$

In this expression, we have included the higher-order corrections for $C_{\pm}$ appearing in the velocity $[f_N^{(\pm)}(q) \equiv v_{\pm} q_{\parallel} + C_N^{(\pm)} |q|^2 q_{\parallel} + \ldots]$, the noise $[f_N^{(\pm)}(q) \equiv N_{\pm} \tilde{\rho} |q|^2 + C_{N,\pm} q_{\parallel} + \ldots]$, and the diffusion $[f_D^{(\pm)}(q) \equiv D_{\pm} |q|^4 + C_{D,\pm} q_{\parallel}^2 q_{\parallel}^2 + \ldots]$. Here, $C_D^{(\pm)} \approx 3/16$ and $C_N^{(\pm)} \approx 3/8$, to leading order in $\tilde{\rho}$. We see that $f_D^{(\pm)}(q)$ does not contribute to the static structure factors, so that odd powers of $q$ never appear. Terms like $|q|^3$ in Eq. (7) must be sought from the fluctuation corrections induced by the interaction terms (cubic and higher-order in the fields) in the action $\mathcal{J}$ [Eq. (13)].

Before analyzing fluctuation corrections, it is worth comparing the results of this field-theoretic approach to simulation data for low densities and small drive, where we expect good agreement with the “bare” correlation functions in Eq. (14). Specifically, after inverting back to $(r, t)$, they correspond to Gaussians for $S_{\rho,\psi}(r, t)$. In particular, along the drive direction $[r = (x, \parallel, 0)]$, we find

$$S_{\rho,\psi}(r, t) = \frac{N_\pm \tilde{\rho}}{4\pi D_{\pm} t} \exp \left[ -\frac{(x - v_{\pm} t)^2}{4 D_{\pm} t} \right], \quad (16)$$

with the plus (minus) signs for the density (charge) case. This form is consistent with the simulation results shown in Fig. 8. Fitting these curves to drifting Gaussians, we can extract simulation values for $v_\pm/\delta$ and $D_{\pm}$. These can be compared with theoretical values, estimated beyond the lowest order in $\tilde{\rho}$ by using the Doi-Peliti approach (see Appendix A): $v_\pm/\delta = e^{-3\tilde{\rho}}[1(1 - \tilde{\rho})^2 + 2(1 - \tilde{\rho})^2]/4$ and $D_{\pm} = e^{-3\tilde{\rho}}(1 + 2e^{\tilde{\rho}^2})(\tilde{\rho} + 3\bar{\rho}^2)/8$. The comparison is shown in Fig. 9 with $v_+/\delta$, $D_+$ indicated by dashed red lines and $v_-/\delta$, $D_-$, by solid blue. Given that we relied on only the lowest possible order in the field-theoretic approach, it is remarkable how well the predictions fare, especially at small $\tilde{\rho}$. Note that at larger densities $\tilde{\rho}$ that approach the phase transition, our mean-field results predict a vanishing $D_+$, which is not observed in the simulation results [see Fig. 9(b)]. We thus expect the perturbation theory for the fluctuation corrections developed in the next section to break down near the phase transition, where other techniques (e.g., the renormalization group) have to be employed.

We end this section with some comments on the aspects of our driven lattice gas which may be understood in terms of a “bare” theory. The velocities of the two fields are different, with that of the density-field being lower: $v_+ < v_-$. Though the theoretical value seems to vanish at some special $\tilde{\rho}$, it is unclear if this point is of any physical significance. We should remind ourselves that this is the velocity of the fluctuations and not the density itself. Such is a common experience in traffic, where local jams (fluctuations of higher density) are often observed to travel “backwards” from the direction of the drive. The two diffusion coefficients $D_{\pm}$ also differ in general. Though $D_+ > 0$ for all values of $\tilde{\rho}$, $D_-$ vanishes at some point, as mentioned above. Ordinarily (in both equilibrium systems and DDS), this is a signal of criticality and onset of phase separation. However, a vanishing coefficient of $q^2$ cannot describe the transition into stripes observed. Instead, there must be a divergence of $S_{\psi}(q)$ at $|q|| = 2q_0^*$ (to accompany the divergence of $S_{\psi}(q)$). Nevertheless, for densities far below criticality, this theory does capture the drifting and diffusive behavior of both kinds of fluctuations.
Note that the difference in velocities $v_d = v_+ - v_-$ being non-zero is a key feature of the model. As a result, it is not possible to choose a co-moving frame in which both densities suffer no drift. In technical terms, we cannot eliminate both drift terms from the Langevin equations for $\phi_\pm$, Eq. (12), so that one of them must be involved when we consider the fluctuation corrections. The presence of a drift term is not only a major difference between the field-theoretic formulation for our model and that for DDS [52, 53], but also appears to be the key ingredient for the emergence of spatial structures periodic along the drive.

To summarize, mean-field theory (i.e., the quadratic part of $\mathcal{J}$) provides us with static structure factors of the form

$$S_{\rho, \psi}(\mathbf{q}) = \frac{N_\pm |\mathbf{q}|^2}{D_\pm |\mathbf{q}|^2 + C_D^{(\pm)} |\mathbf{q}|^4 + C_D^{\|} |\mathbf{q}|_\perp^2},$$

(17)

which is clearly inadequate for generating the characteristic “microemulsion” peaks in $S_\psi$ when $\delta > 0$. These peaks can only arise from the fluctuation corrections (with $v_d \neq 0$ playing a key role), which will be our focus in the next section.

V. FLUCTUATION CORRECTIONS

Corrections due to fluctuations can be developed using a perturbative approach, starting with the quadratic terms in the action $\mathcal{J}$ [i.e., a “free” field theory, with the correlation functions in Eq. (14)]. In this work, we restrict our attention to how these two-point functions are modified by the cubic terms in $\mathcal{J}$, i.e., those with $g_{0, \pm} \propto \delta$: $\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cd\...
In two dimensions, we can generally expect (logarithmic) divergence at both the UV and IR ends. As we plan to compare our results to simulation data on a finite lattice, we will simply impose an UV cutoff, $\Lambda$, and evaluate at non-zero wavenumbers [specifically, $q_\parallel \sim O(1/L)$]. In fact, since both densities are conserved, $S_{\rho,\psi}(q=0)$ are fixed \[10\].

Turning first to the self-energy $\Sigma_-(q,\omega)$ for the charge field, we see that the lowest order corrections (i.e., with one loop, $\propto \delta^2$) are, in terms of diagrams, given by

$$
\Sigma_-(q,\omega) = \begin{array}{c}
\text{diffusive part} \\
\text{drift part}
\end{array} + \begin{array}{c}
\text{diffusive part} \\
\text{drift part}
\end{array}
$$

(21)

$$
= \int d\omega_k\,dk\,\{g_0 g_- + g_0^2\}.
$$

(22)

The key feature of the loop integration is the mixing of the propagators for the charge and density fields [dashed and solid lines in Eq. (21)] which prevents us from eliminating the linear drift terms $v_\pm k_\parallel$ in both propagators simultaneously. In the usual single-species DDS case, for example, a Galilean transformation into a co-moving frame removes the linear drift term. This is not possible here as the charge and density fields have different characteristic velocities $v_\pm$. Indeed, as will be shown below, $v_\perp \equiv v_+ - v_-$ plays the key role for characterizing the periodic structures. A similar phenomenon occurs in a model for drifting crystals treated in Ref. \[62\], which also has two scalar fields with different drift velocities.

Substituting in the propagators from Eq. (14) and evaluating the integrals, we find, to leading order in the average density $\bar{\rho}$,

$$
\Sigma_- \approx g_0 N \bar{\rho} v_d q_\parallel \left\{ \frac{2(g_- - g_0)q_\parallel}{q_c} - \frac{i(g_- + g_0)}{2} \right\}
\times \ln \left[ \frac{(4\Lambda)^2}{2i(\bar{\rho}q_\parallel - \omega)/D + q_c^2 + |q|^2} \right] + i(g_- + g_0),
$$

(23)

where

$$
q_c \equiv \frac{v_d}{2D}
$$

(24)

is a crossover wavenumber that will be prominent in our discussions below. From this complex expression, it is instructive to study the real and imaginary parts of $\Sigma_-$ (with real $q$ and $\omega$ separately, as they enter into the diffusive and drift parts of Eq. (20), respectively). As discussed above, Re $\Sigma_-$ plays a more significant role for $S_\psi$ and it reads

$$
\text{Re } \Sigma_- = \frac{N \bar{\rho} g_0}{32\pi D^2} \left\{ (g_- - g_0)q_\parallel^2 \ln \left[ \frac{(4\Lambda)^4}{2(\bar{\rho}q_\parallel - \omega)/D + q_c^2 + |q|^2} \right] - 2(g_- + g_0)q_c q_\parallel \tan^{-1} \left[ \frac{2(\bar{\rho}q_\parallel - \omega)/D}{q_c^2 + |q|^2} \right] \right\}.
$$

(25)

The first term in the curly braces, proportional to $q_\parallel^2$, would renormalize the diffusivity $D_-$ in the drive direction. It introduces a DDS-like anisotropy and leads to a potential discontinuity in the static structure factor at $q = 0$. The second term, with coefficient $q_c q_\parallel \propto v_d q_\parallel$, has no DDS analog. Of course, an integration over $\omega$ is needed to obtain the static $S_\psi(q)$. But, as noted above, we can find a rough estimate of its effect by evaluating this term in the co-moving frame (by setting $\omega = v_- q_\parallel$ in this case). The result is $\propto q_c q_\parallel \tan^{-1} (q_c q_\parallel/ (q_c^2 + |q|^2))$, confirming that it is necessarily even in $q_\parallel$. Yet, it provides the signal of a crossover: For small $q_\parallel$, it starts as $q_\parallel^2$, but it behaves as $v_{\parallel} q_\parallel$ for values around $q_c$ (where the $\tan^{-1}$ is slowly varying). This is the property that offers the possibility of a maximum in $S_\psi$, as we shall see. By contrast, the imaginary part, Im $\Sigma_-$, does not affect $S_\psi$ qualitatively and the result may be found Appendix B.

Turning to the correction to the noise in $\bar{\rho} q_\parallel$, we see that the relevant diagram is

$$
\eta_- = \begin{array}{c}
\text{diffusive part} \\
\text{drift part}
\end{array} = \int d\omega_k\,dk\,\{g_0^2\}
$$

(26)

with the result

$$
\eta_- \approx \frac{g_0^2 N^2 \bar{\rho}^2}{8\pi D^3} q_\parallel^2 \ln \left[ \frac{(4\Lambda)^4}{2(\bar{\rho}q_\parallel - \omega)/D + q_c^2 + |q|^2} \right].
$$

(27)

As may be expected, $\eta_-$ is real and, being proportional to $q_\parallel^2$, introduces an anisotropy in the noise correlations. Note that every correction vanishes with $q_\parallel$ so that $S_\psi(q_\parallel = 0, q_\perp)$ suffers no modifications (at least at this lowest order). In other words, there are no changes for the structure factors perpendicular to the drive. This is a feature our model shares with the single-species DDS, leading to a discontinuity singularity at $q = 0$.

When all these corrections are inserted into Eq. (20) and the $\omega$ integration performed numerically, we find that the modification to the structure factor is positive, as illustrated by the $\delta \neq 0$ curves for $S_\psi(q_\parallel = 0, q_\perp)$ in Fig. 10(a). Thus, we recover the DDS-like discontinuity observed in simulations (see Fig. 5): $S_\psi(q_\parallel \rightarrow 0, q_\perp = 0) > S_\psi(q_\parallel = 0, q_\perp = 0)$. More crucially, as we examine $S_\psi(q_\parallel, q_\perp = 0)$ at larger $q_\parallel$, we find that the effectively $|q_\parallel| \propto v_\perp$ behavior in the fluctuation corrections creates a peak
Suture factors for the density fields, $\delta$, may be coincidental, as only the lowest orders in $q_\parallel$ with simulation results. Of course, this good agreement is not evident for the $\delta$ over to a smooth $q_\perp=0$ case [inset of Fig. 10(a)]. By contrast, there is no hint of such smoothing in the data, Fig. 10(a) (although this feature may reveal itself in larger systems). Turning to the peak position, our theory finds a kink with a positive slope ($\delta=0.6$ case [downwards as $q_\parallel \rightarrow 0$, in Fig. 10(a)] for the $S_\psi$’s, the data here show a cusp$^3$ with a large negative slope (upwards), which is especially prominent in the $\delta = 0.02$ case. This feature is certainly displayed in the theoretical $S_\psi$’s. Indeed, it is straightforward to uncover an IR divergence associated with the integrals regularized by $q_\parallel \neq 0$. In this case, we expect a singularity of the form of $\ln q_\parallel$ in $S_\rho$. To probe this property further, we plot $S_\rho(q_\parallel, 0)$ vs.

\[ \Sigma_+ = \sum \frac{g_0 g_\pm g_\mp}{2(v_\perp - \omega)/D_+ - i|q|^2} \]

and

\[ \eta_+ = \sum \frac{g_\pm g_\mp g_\pm}{2(v_\perp - \omega)/D_+ + |q|^2} \]

and noise corrections are similar to those above:

\[ \Sigma_+ = \int d\omega_k \, d\mathbf{k} \{ g_0 g_\pm g_\mp \} \]

\[ \eta_+ = \int d\omega_k \, d\mathbf{k} \{ g_\pm g_\mp g_\pm \} . \]

The results are

\[ \Sigma_+ = \frac{\mu q_\parallel^2}{16\pi} \ln \left[ \frac{(4\Lambda)^2 e^{-i\pi/2}}{2(v_\perp - \omega)/D_+ - i|q|^2} \right] \]

\[ - g_\pm^2 N_+ \frac{D_+}{2i(v_\perp q_\parallel - \omega) + |q|^2} \]

and

\[ \eta_+ = \frac{\mu q_\parallel^2}{32\pi} \ln \left[ \frac{g_\pm^2 N_\alpha^2}{D_\alpha^3} \right] \]

\[ \times \ln \left[ \frac{(4\Lambda)^4}{2(v_\perp q_\parallel - \omega)/D_\alpha + |q|^4} \right] \].

It is instructive to compare these corrections to the ones for the charge fields, $\Sigma_-$ and $\eta_-$. In the latter, the small $\omega$, $q_\parallel$ behavior is regulated by $q_\perp$ (i.e., the velocity difference $v_{a\parallel}$). By contrast, we find logarithmic divergences in the IR regime for $\Sigma_+$ and $\eta_+$. When inserted in Eqs. (20) and the integration carried out, these generate the cusp-like structures in $S_\rho$ as $q_\parallel \rightarrow 0$. In Fig. 10(b), we illustrate $S_\rho(q_\parallel, 0)$ for various drives. Quantitatively, there is little agreement between these $S_\psi$’s and the simulation values in Fig. 10(b). Nevertheless, we call attention to two important qualitative features: One is that, when driven, the fluctuations modify the small $q_\parallel$ behavior considerably. Instead of a kink with a positive slope (upwards), which is especially prominent in the $\delta = 0.02$ case. This feature is certainly displayed in the theoretical $S_\psi$’s. Indeed, it is straightforward to uncover an IR divergence associated with the integrals regularized by $q_\parallel \neq 0$. In this case, we expect a singularity of the form of $\ln q_\parallel$ in $S_\rho$. To probe this property further, we plot $S_\rho(q_\parallel, 0)$ vs.

\[ ^3 \text{We have reasons (see below) to believe that } S_\rho \text{ diverges as } \ln q_\parallel, \text{ so that the slope will diverge as } q_\parallel \rightarrow 0. \] Thus, we use the term “cusp” instead of “kink” here.

Finally, we consider the corrections to the static structure factors for the density fields, $S_\rho(q)$. Again, we defer the details of the calculation to Appendix B and present only some highlights here. The graphs for the self-energy at a non-trivial $q_\parallel^*>0$. However, the theoretical result does not have a $|q_\parallel|$-like kink at the origin, but crosses over to a smooth $q_\parallel^*$. This “rounding off” is especially evident for the $\delta = 0.6$ case [inset of Fig. 10(a)]. By contrast, there is no hint of such smoothing in the data, Fig. 10(a) (although this feature may reveal itself in larger systems). Turning to the peak position, our theory finds $q_\parallel^* \approx 0.398|q_\parallel| \approx 1.26|\rho|\delta$. Note that it is proportional to the drive magnitude $|\delta|$ and the particle density $\rho$. To compare this expression with data, we obtain a linear fit to the red points in Fig. 4 (2D) for small $|\delta|$ and found $q_\parallel^* \approx 0.64|\delta|$ (red line). Since the data are from a system with $\rho = 0.5$, the theoretical value would be $q_\parallel^* \approx 0.63|\delta|$, which is in surprisingly good agreement with simulation results. Of course, this good agreement may be coincidental, as only the lowest orders in $\rho$ and $\delta$ have been kept in the field theoretic treatment.
dimension for singularities appears in dynamics, as anomalous diffusive system in the disordered phase. There, the static display a behavior linear in \( \ln q \), where we find a horizontal line (light blue lines and convergence, predicted by the field theory, which vanishes when \( \delta > 0 \)). The leading order corrections considered here reproduce the qualitative features of the structure factors for both the charge and density fields. In this sense, we believe that the approach developed here is a sound first step towards a quantitatively successful theory. The next steps would take into account the renormalization of all of the relevant couplings in Eq. (13). Although beyond the scope of the current work, pursuing a systematic analysis is a worthy goal. When completed, we are confident that the surprising properties of the DWRLG can be understood.

VI. SUMMARY AND OUTLOOK

Exploiting Monte Carlo and field-theoretic techniques, we analyzed a strongly-driven lattice gas with two species \((A, B)\) – the Widom Rowlinson model. Restricting ourselves to systems with equal numbers of each species, there are only two control parameters: the overall particle density, \( \bar{\rho} \), and the drive, \( \delta \). As the system settles into non-equilibrium steady states, many unexpected properties emerge. As both control parameters increase, the homogeneous phase gives way to phase-separation, with order stripes (slabs in 3D) perpendicular to the drive. The precursor of this transition appears as a “patterned” disordered phase, characterized by a non-trivial wavelength associated with the drive direction. Specifically, the static structure factor \( S^\psi(q_{||}, 0) \) (for the difference in local densities: \( \psi = \rho_A - \rho_B \)) has a peak at \( q_{||} = 0 \), as illustrated in Fig. 11 for both the data (a) and theoretical results (b). Surprisingly, for small \( q_{||} \), both display a behavior linear in \( \ln q_{||} \). We caution that such a behavior should not be extrapolated naively. It is likely that more subtle physics comes into play at larger scales and that higher order corrections will be important.

Note that these divergences (\( \ln q_{||} \) in \( d = 2 \)) are reminiscent of the behavior of the single species driven diffusive system in the disordered phase. There, the static structure factors are regular in the IR limit, while the singularities appears in dynamics, as anomalous diffusion for \( d \leq d_c = 2 \) [14, 60]. We believe it is the presence of two different drift velocities in our model (which prevents us from studying the system in a co-moving frame) which allows the dynamic singularities to induce the ones in static quantities. It would be interesting, but beyond the scope of this paper, to find such connection and to explore how anomalous diffusion manifests in the DWRLG.

Before ending this section, note that the \( S_\rho \)'s [in Fig. 7 or 10(b)] do not display peaks like the ones in the charge \( S^\psi \)'s. Yet, as the overall density approaches the critical value and stripes form, \( S^\psi(q_{||}, 0) \) will diverge and so must \( S_\rho(q_{||}, 0) \). Thus, peaks in the latter must develop. We believe that, for the values of \( \bar{\rho} \) and \( \delta \) shown here, such peaks are shrouded by the logarithmic divergence near the origin. Indeed, for the largest drives illustrated, there is a detectable shoulder in the theoretical \( S_\rho \) [red curve for \( \delta = 0.6 \) in Fig. 10(b)] and the hint of one in the data [purple curve for \( \delta = 0.5 \) in Fig. 7].
the latter, the drive produces a single drifting $v$ associated with the local density field. By contrast, due to the excluded volume interactions (between $A$ and $B$), the drive in the DWRLG induces two different drift velocities (for $\rho, \psi$). The peak in $S_\psi$ can be traced to the ratio of this velocity difference and the average diffusivity: $v_d/D$. For deeper reasons we have yet to find, this aspect also appears to allow the dynamic singularities associated with the local density field. By contrast, due to which our simple theory cannot accommodate. The high malization of the couplings of the theory.

For larger than criticality. In the previous study [10], investigating the critical behavior observed in Ref. [10]. On the simulations front, improved studies with larger systems are underway so that various exponents, as well as the likely presence of anisotropic scaling, can be better measured. There is also much of interest in system at densities larger than criticality. In the previous study [10], interfaces are found to display Edwards-Wilkinson-like behavior [63]. How can such behavior be understood, as these interfaces are drifting due to the drive and not part of a system in thermal equilibrium? Apart from understanding how (and at what densities) configurations with $N$ stripes can evolve into $N - 1$ stripes, we may consider the extreme high density limit. There, the system consists of just two regions with particles of $A$ or $B$ only (separated by thin lines of vacancies) and a handful of holes drifting through. These “drifters” interact with the interfaces, of course. Other than that, their travels through the “bulk” regions must be identical to the ordinary single-species DDS. Their interactions with the interfaces drive the latter, in a manner reminiscent of the Eden model of growing interfaces [64]. Simulation studies can be readily carried out, but our hope is that some theoretical progress is also possible in what appears to be a “minimal” system.

Beyond the particular system studied here, we should explore the vast, and likely novel, territory associated with “non-neutral” systems ($\bar{\rho}_A \neq \bar{\rho}_B$). There is also the question of whether the presence of an underlying lattice plays a crucial role. For answers, we may explore molecular dynamics simulations in a continuum, modeling colloidal particles with repulsive interactions suspended in a solvent and driven with an applied force. The hope is that connections between such computational and theoretical work can be established with physical experimen-

**ACKNOWLEDGMENTS**

**Appendix A: Doi-Peliti formalism**

The probability distribution $P(\{\sigma_x\}, t)$ of observing particle configuration $\{\sigma_x\}$ at time $t$ is conveniently represented by introducing a vector $|P\rangle$ defined as

$$|P\rangle = \sum_{\{\sigma_x\}} P(\{\sigma_x\}, t) |\{\sigma_x\}\rangle,$$

where $|\{\sigma_x\}\rangle$ is the lattice state in the occupation number representation. Then, the master equation may be represented via a Schrödinger-like equation which reads

$$\partial_t |P\rangle = -\mathcal{L}|P\rangle,$$

where the Liouville operator $\mathcal{L}$ (or pseudo-Hamiltonian) will depend on the rates given by Eq. [5]. To construct the operator $\mathcal{L}$, we introduce creation and annihilation operators $a_x^\dagger$ and $a_x$, respectively. These increase or decrease by one the occupation number of the $A$ species at site $x$ and satisfy the commutation relations $[a_x, a_y^\dagger] = \delta_{x,y}$. We also need an equivalent set $[b_x, b_y^\dagger] = \delta_{x,y}$ for the $B$ species, both of which will commute with the $A$ species operators. By applying the creation operators to the state $|0\rangle$ with no particles (the vacuum), we may place as many particles as we wish at any of the lattice sites $x$. This is a problem, however, as our model is constrained by the excluded volume and particle repulsion rules, which must somehow be taken into account.

To incorporate both the excluded volume and the nearest-neighbor exclusion rule, we follow van Wijland [60] and introduce delta function operators $\delta_{n_x}^{A,B,m}$ (where $m = 0, 1, 2, \ldots$ and $n_x^{A,B} = a_x^\dagger a_x b_x^\dagger b_x$) which have the particle states $|\{\sigma_x\}\rangle$ as eigenvectors with eigenvalues $\delta_{n_x}^{A,B,m}$, where $n_x^{A,B}$ is the number of $A$ or $B$ particles at site $x$. It is now straightforward to write down the operator $\mathcal{L}$ as the delta function operators can guarantee that any hopping transition that violates the excluded volume or nearest-neighbor exclusion rules will vanish. The operator reads
\[ L = \frac{1}{8\tau} \sum_{x_{\pm} = \pm 1} \left\{ (1 + \epsilon \delta)(a_{x_{\pm} - \epsilon \ell_{x}}^{\dagger}x_{\pm} - a_{x_{\pm} - \epsilon \ell_{x}}) \delta_{x_{\pm} - \epsilon \ell_{x}} \right. \\
+ \left. (a_{x_{\pm} - \epsilon \ell_{x}}^{\dagger}x_{\pm} - a_{x_{\pm} - \epsilon \ell_{x}}) \delta_{x_{\pm} - \epsilon \ell_{x}} \right\} \delta_{x_{\pm} + \epsilon \ell_{x}} \delta_{x_{\pm} + \epsilon \ell_{x}}, 0 \\
+ \sum_{\ell = \pm 1} (1 + \delta)(a_{x_{\pm} - \epsilon \ell_{x}}^{\dagger}x_{\pm} - a_{x_{\pm} - \epsilon \ell_{x}}) \delta_{x_{\pm} - \epsilon \ell_{x}} \delta_{x_{\pm} - \epsilon \ell_{x}}, 0 \delta_{x_{\pm} + \epsilon \ell_{x}}, 0 \delta_{x_{\pm} + \epsilon \ell_{x}}, 0 \right\} \delta_{\epsilon \ell_{x}}, 0 \delta_{\epsilon \ell_{x}}, 0 + (a, A) \leftrightarrow (b, B), \quad (A3) \]

where \( \tau \) is the lattice update time step, \( \ell_{\parallel} = \ell \bar{x} \) is the lattice spacing in the drive direction and \( \ell_{\perp} = \ell y \) is the lattice spacing in the perpendicular direction. Note that we get another set of the same terms for the \( B \) particle motion which can be generated by replacing \( a \) and \( A \) with \( b \) and \( B \), respectively. Note that Eq. (A2) with the Liouville operator given in Eq. (A3) represents the microscopic lattice dynamics exactly. The rates \( \dot{\psi}_{x_{\pm}+\epsilon \ell_{x},\pm} \) in Eq. (A2) are incorporated directly in Eq. (A3), where we specialize here to the square lattice for which \( N_n = 8 \) is the number of NN and NNN sites.

To obtain the densities within the Doi-Peliti formalism, one first introduces coherent states \( |\phi_A, B \rangle \), which are eigenstates of the annihilation operators: \( a_{x} |\phi_A, B \rangle = \phi_{x}^A |\phi_A, B \rangle \) (with a similar relation for species \( B \)), where \( \phi_{x}^A \) is a complex eigenvalue. The time evolution in Eq. (A2) can then be represented as a path integral over coherent state field configurations \( \phi_{x}^{A, B} \) using standard techniques [65]. The coherent states may be related to the particle densities \( \rho_{x}^{A, B} \) at lattice site \( x \) via a Cole-Hopf transformation \( |\phi_{x}^{A, B} \rangle = e^{\hat{\phi}_{x}^{A, B}} \) and \( \phi_{x}^{A, B} = e^{-\hat{\phi}_{x}^{A, B}} \), where \( \rho_{x}^{A, B} \) is the conjugate or response field to the densities \( \rho_{x}^{A, B} \) at site \( x \). One then generates a joint action \( J = \int J[\rho_{x}^{A, B}, \rho_{x}^{B, A}] \) that facilitates the computation of averages over stochastic trajectories of any functional \( O[\rho_{x}^{A, B}] \) just as in Eq. (11) in the main text. If we write the local densities as \( \rho_{x}^{A, B} = \bar{\rho}_{x}^{A, B} + \psi_{x}^{A, B} \) at each lattice site \( x \), with \( \bar{\rho}_{x}^{A, B} \) the average contribution (so that \( \sum_{x} \psi_{x}^{A, B} = 0 \)), the Doi-Peliti action reads

\[ J = \frac{\epsilon}{\tau} \int dt \sum_{x} \left[ \dot{\psi}_{x}^{A, B} \partial_{t} \psi_{x}^{A, B} + \dot{\psi}_{x}^{B, A} \partial_{t} \psi_{x}^{B, A} + H_{x} \right], \quad (A4) \]

where \( \dot{\psi}_{x}^{A, B} \) are the response fields and \( H_{x} \) is a local pseudo-Hamiltonian density that encodes the particle exclusions and hopping rates, derived from the analogous terms in the Liouville operator \( L \) in Eq. (A3) by taking the expectation value of \( L \) with respect to the coherent states. This development is described in standard texts, e.g., Ref. [65].

To write down the density \( H_{x} \) explicitly for a two-dimensional lattice, it is convenient to introduce discrete derivative operators of any function \( f(x) \) defined on the lattice sites \( x = (x, y) \): \( \Delta_{i,j} f(x) \equiv f(x + i \ell_{\perp} + j \ell_{\parallel}) - f(x) \), where \( \ell_{\perp, \parallel} \) are the lattice spacing along and perpendicular to the drive. In terms of these discrete derivative operators, we have, dropping the \( x \) subscripts for notational convenience (so that \( H \equiv H_{x} \) and \( \psi_{x}^{A,B} \equiv \psi_{x}^{A,B} \)), with the last term \( A \leftrightarrow B \) indicating that we need to add all the previous terms with the two particle types switched. The terms in Eq. (A5) have a certain logic: The first term (first three lines) corresponds to hops along the \( x \)-axis, while the second term (fourth and fifth lines) represents the \( y \)-axis hops. Finally, the double summation over \( \epsilon, l = \pm 1 \) (lines six through eight) represents the hops to the four NNN lattice sites. A similar formulation is straightforward for the three-dimensional case, except there are sixteen possible hopping locations.

This formulation, while derived exactly from the lattice hopping rules, is inconvenient for understanding the coarse-grained features of the system. We next need to move to a continuous description and introduce the local, coarse-grained particle densities \( p_{i,j}^{A,B} \). It will be here where the method becomes approximate, necessitating careful checks against simulation results. We begin with the Doi-Peliti action, given by Eq. (A4), with the discrete pseudo-Hamiltonian in Eq. (A3). We move to a continuous coordinate \( x \rightarrow r \) and assume the fluctuation fields \( \psi_{x}^{A, B} \) are slowly varying on the scale of the lattice spacing \( \ell \), so we may replace them (and the corresponding response fields) with continuous fields \( \psi_{x}^{A, B} \equiv \psi^{A, B}(r, t) \) at any time \( t \) in the evolution. Then, the discrete derivative operators \( \Delta_{i,j} \) defined above can be expanded in gradients with respect to \( r \). The expansion up to quadratic terms in \( \ell \) is

\[ \Delta_{i,j} \approx i \ell_{\perp} \partial_{\perp} + j \ell_{\parallel} \partial_{\parallel} + \frac{\ell^2 \partial_{\perp}^2}{2} + \frac{\ell^2 \partial_{\parallel}^2}{2} + ij \ell_{\perp} \partial_{\parallel} \partial_{\perp}, \quad (A6) \]
where $i, j$ are the integers representing the square lattice locations $x = \ell(i, j)$.

Eq. (A6) is substituted into Eqs. (A4A5) and we expand in powers of the fields and the lattice spacing $\ell$. We then perform a field redefinition and introduce the charge and density field fluctuations $\phi_\pm \equiv \phi \pm (r, t)$, which are defined via $\phi_\pm = \psi^A \pm \psi^B$, with corresponding response fields $\phi_\pm = \psi^A \pm \psi^B$. Then, introducing the total particle density $\bar{\rho} = \bar{\rho}^A + \bar{\rho}^B$, we find that Eq. (A4) reduces in the continuum limit to the action given by Eq. (13) for the equal density case $\bar{\rho}_A = \bar{\rho}_B = \bar{\rho}/2$, with all of the coupling definitions stated in the main text.

### Appendix B: Details of fluctuation corrections

In this appendix we give a few other details of the computation for the corrections to both the self-energy ($\Sigma_\pm$) and noise ($\eta_\pm$) terms. For $\Sigma_\pm \equiv \Sigma_\pm(\mathbf{q}, \omega)$, the two integrals, shown diagrammatically in Eq. (21), are

$$
\Sigma_\pm = \int \frac{d\omega_k}{(2\pi)^3} g_\omega \left[ \frac{k^2}{2} + k_\perp q_\parallel \right] \left\{ g_- C_- \left[ \frac{q}{2} - k, \omega - \omega_k \right] G_+ \left[ \frac{q}{2} + k, \omega + \omega_k \right] - g_0 C_+ \left[ \frac{q}{2} - k, \omega + \omega_k \right] G_- \left[ \frac{q}{2} + k, \omega + \omega_k \right] \right\}. \quad (B1)
$$

The key feature here is the mixing of the propagators for the charge and density fields [dashed and solid lines in Eq. (21)] which prevents us from eliminating the linear drift terms $v_\perp k_\parallel$ in both propagators simultaneously, unlike the case in the single-species DDS. Substituting in the expressions in Eq. (14), we evaluate the integral over $\omega_k$ first. To simplify calculations, we dropped the terms quartic in $\mathbf{q}$ (which would have provided a UV cutoff $\Lambda$ we introduce below). The result is

$$
\Sigma_\pm \approx \int \frac{d\mathbf{k}}{(2\pi)^3} \bar{\rho}_0 g_\omega \left[ \frac{q}{2} - k_\parallel \right] \left[ g_\omega \left[ \frac{q}{2} - k_\parallel \right] - g_0 \left[ \frac{q}{2} + k_\perp \right] \right] \frac{\bar{N}}{D^2} \left[ \frac{\ln (2(\bar{\rho}^A - g_-) - iD) [\omega - i(q_\parallel - \omega)]^2}{2D_\perp (q_\parallel^2 + |\mathbf{k}|^2)} - \frac{\ln (2(\bar{\rho}^A - g_-) - iD) [\omega - i(q_\parallel - \omega)]^2}{2D_\perp (q_\parallel^2 + |\mathbf{k}|^2)} \right]. \quad (B2)
$$

to leading order in the average density $\bar{\rho}$. After integrating $k_\perp$ on the real line first, the remaining $\int k_\parallel$ is naively linearly divergent. However, by imposing the UV cutoff $\Lambda = \pi/\ell$, we find the result in the main text:

$$
\Sigma_\pm \approx \frac{\bar{\rho}_0 \bar{N}}{D^2} \left[ \left\{ \frac{q_\parallel}{q_\parallel - g_0} (g_- - g_0) - i(g_- + g_0) \right\} \ln \left[ \frac{16A^2}{2i(q_\parallel - \omega)/D + q_\parallel^2 + |\mathbf{q}|^2} \right] + i(g_- + g_0) \right] \left. \right\}_{q_\parallel = v_d/2D} \quad (B3)
$$

Here, $D = (D_+ + D_-)/2$ is the average diffusivity, $\bar{v} = (v_+ + v_-)/2$ the average velocity, $v_d = -\bar{\rho}_0$ the velocity difference, $q_\perp = v_d/2D$ the crossover wavenumber, and $\bar{N} = (N_- + N_+)/2$ is the noise correlation magnitude. The real part, $\Re \Sigma_\pm$, is given in Section V. For completeness, we provide the imaginary part here:

$$
\text{Im} \Sigma_\pm = \frac{\bar{\rho}_0 \bar{N}q_\parallel}{16\pi D^2} \left\{ \left( g_0 - g_- \right) q_\parallel \text{tan}^{-1} \left[ \frac{2(\bar{\rho}_0 - \omega)}{D(q_\parallel^2 + |\mathbf{q}|^2)} \right] - \frac{\left( g_0 + g_- \right) q_\parallel \text{ln} \left[ \frac{2^{12}D^2 d^4 e^{-4\pi\rhoq_\parallel}}{|\mathbf{q}|^2 + 16D^2[q_\parallel^2 + |\mathbf{q}|^2]^2} \right]}{2} \right\}. \quad (B4)
$$

Meanwhile, the single integral associated with the noise correction for the charge field is

$$
\eta_\pm \approx \frac{\bar{N} \bar{\rho}_0 q_\parallel^2}{D} \int \frac{d\mathbf{k}}{(2\pi)^2} \left\{ \frac{N_- g_\pm g_0}{2} \frac{-2(\bar{\rho}^A - g_\pm) - iD} {2D_\perp (q_\parallel^2 + |\mathbf{k}|^2) - iD} \right\} \quad (B5)
$$

Similarly, after the $\omega_k$ integration, we find the self-energy for the density field, represented by Eq. (28), to be

$$
\Sigma_\pm \approx \frac{\bar{\rho}_0 q_\parallel^2}{2} \int \frac{d\mathbf{k}}{(2\pi)^2} \left\{ \frac{N_- g_\pm g_0}{2} \frac{-2(\bar{\rho}^A - g_\pm) - iD} {2D_\perp (q_\parallel^2 + |\mathbf{k}|^2) - iD} \right\}, \quad (B6)
$$

leading to the result in Eq. (30). For completeness, we display its real and imaginary parts:

$$
\text{Re} \Sigma_\pm \approx \frac{\bar{\rho}_0 q_\parallel^2}{32\pi} \left\{ \frac{N_- g_\pm g_0}{D^2} \frac{256A^4}{D} \left[ \frac{2}{2\pi (\bar{\rho}^A - g_\pm) - \omega) + |\mathbf{q}|^2} \right] \right\} \quad (B7)
$$

and

$$
\text{Im} \Sigma_\pm \approx \frac{\bar{\rho}_0 q_\parallel^2}{16\pi} \left\{ \frac{N_- g_\pm g_0}{D^2} \frac{256A^4}{D} \left[ \frac{2}{2\pi (\bar{\rho}^A - g_\pm) - \omega) + |\mathbf{q}|^2} \right] \right\} \quad (B8)
$$

Finally, the correction to the noise correlations, $\bar{N}_+ = N_+ \bar{\rho}^A q_\parallel^2 + \eta_+$ [associated with Eq. (29)] is given by

$$
\eta_+ \approx \frac{\bar{\rho}_0 q_\parallel^2}{4} \int \frac{d\mathbf{k}}{(2\pi)^2} \left\{ \sum_{\alpha = \pm} \frac{\bar{\rho}_0 q_\parallel^2}{(\omega - v_\alpha k_\parallel)^2 D_\alpha^2 + D_\alpha^2 [q_\parallel^2 + |\mathbf{k}|^2]^2} \right\}, \quad (B9)
$$

which leads to the result in Eq. (31).
