Malignant melanoma among lithographers

by Henrik Nielsen, MD,1 Leif Henriksen, MD,2 Jørgen H Olsen, MD3

Nielsen H, Henriksen L, Olsen JH. Malignant melanoma among lithographers. Scand J Work Environ Health 1996;22:108-11.

Objectives Mortality studies have suggested that workers in the printing industry may have a higher incidence of malignant melanoma. The aim of this study was to assess the incidence of malignant melanoma among lithographers.

Methods A cohort of 837 lithographers, born in 1933—1942, was followed in the Danish Cancer Register from 1974 to 1989.

Results Five cases of malignant melanoma were found, with 1.5 expected (relative risk 3.4, 95% confidence interval 1.2—7.5).

Conclusions Many known and suspected carcinogens are used in the printing industry. Hydroquinone, used for photographic development, may be implicated in the observed increase in risk, as it causes depigmentation and changes in melanocytes in the skin.

Key terms cancer risk, hydroquinone.

Occupational mortality studies have shown an increased incidence of malignant melanoma in the printing industry or in the printing trades. Dubrow (1) estimated a combined relative risk of 1.98 for this malignancy (based on 23 cases) from nine earlier studies. This finding was surprisingly not confirmed in two large record-linkage studies of occupational cancer in Denmark. The first study analyzed the employment histories of 94,000 cancer patients diagnosed in 1970—1979 (2); the second linked the 1970 census population to the files of the Danish Cancer Registry for the period 1970—1980, comprising 115,000 cancers (3). The present study of cancer risk was based on a cohort of 837 lithographers who started work in the trade between 1947 and 1977. The cohort was established initially to investigate risk for brain damage from exposure to organic solvents. [Those results have been given elsewhere (4).] The group was studied carefully to detect exposures to chemicals used during the study period.

Subjects and methods

Danish lithographers are mainly skilled workers, and more than 90% belong to the Danish Union of Lithographers. The study group thus comprised 837 lithographers, born between 1933 and 1942 (median 51 years, 1989) and registered in the files of the Danish Union of Lithographers as of 1 April 1974 or later. Members who left the Union after that date were retained in the files; one person who could not be traced was excluded from further study. Information on date of emigration or death was obtained from the files of the Danish Central Population Register.

The remaining 836 lithographers were linked to the files of the Danish Cancer Registry, which began reporting incidence data in 1943. The period of follow-up for cancer occurrence was taken from 1 April 1974, or the date of first membership in the Union for those becoming a member later, to the date of death, or 31 December 1989. The total number of cancers registered among the cohort members was recorded for each site. Tumors were classified according to a modified version of the International Classification of Diseases, seventh revision. National incidence rates by gender and five-year age and calendar-year groups for these tumor categories were applied to the appropriate person-years under observation to obtain the number of cancers expected, had the cohort members experienced the same rates of cancer incidences that prevailed in the general population of Denmark. The statistical methods used were based on

the assumption that the observed number of cancer cases in any specific category follows the Poisson distribution. Tests of significance and 95% confidence intervals (95% CI) were calculated for the relative risk (RR), taken as the ratio of the observed-to-expected cancers.

Information on type of work, use of chemicals, and extent of exposure for the cohort members was obtained from a questionnaire mailed in June 1989. Seven questionnaires were not delivered because of a change of address, 32 cohort members were dead, and two had emigrated. The questionnaire was returned by 631 of the 795 persons who received it (a response rate of 79%), and 620 contained enough information to be used in the study.

Exposures

All of the subjects had worked in the printing industry, beginning with exposure to chemicals between 1947 and 1977; 98% of the group had begun work in the trade before 1965. Skilled workers comprised 90% of the study group and had served a full four- to five-year apprenticeship immediately after leaving school. The group had worked steadily within the trade. At the time of the investigation, 96% were active in the labor market (88% employed, 5% unemployed, 4% sick), and the remaining 4% had a disability pension. About half the group worked as offset printers (some were retrained typographers) and the other half in other jobs (eg, reprophotographers, copyists and photoengravers). About 200 lithographers had worked regularly by hand with photographic chemicals and were exposed to hydroquinone.

The subjects' reports indicated that they had been exposed to organic solvents for a mean of 26 years, had used a mean of 26 l of organic solvents per week during cleaning, and had washed plates or machinery for a mean of 32 times a week. Organic solvents mentioned in the questionnaire (number of persons in parentheses) was benzine (489), spirit (379), paraffin (356), turpentine (336), and toluene (307). Other commonly used chemicals mentioned were pigments, dyes, acids, photochemicals, hydroquinone, chromates, and cyanides. More than 2000 products are used in the Danish printing industry (5).

Lithographers have much less exposure to organic solvents and chemicals today than they did earlier. According to the questionnaires, 46% now have no exposure to these compounds in their daily work, and 53% of the workshops have local exhaust ventilation, compared with 5% in the 1950s. Exposure to organic solvents has been markedly reduced because of the use of computer technology and vegetable oils and changes in technical and chemical processes. Film development has been an automatic encapsulated process for a long time, although a variety of chemicals is still used (6).

Results

A total of 24 cancer cases was observed with 26.2 expected, yielding a nonsignificant decreased relative risk of 0.92 for cancer (table 1).

Five cases of malignant melanoma were identified within the study period, while 1.5 were expected (RR 3.4, 95% CI 1.2-7.5); and five cases of nonmelanocytic skin cancer were seen, with 4.4 cases expected (RR 1.1, nonsignificant).

Table 2 gives details for the five cases of malignant melanoma, four of the patients having responded to the questionnaire. The latency from the first exposure as an apprentice to the time of diagnosis was at least 22 years. Two were employed as offset printers and two as photoengravers exposed to hydroquinone. The last patient had worked as a reprocopyist, but we have no information on exposure. They were all alive in 1989, and working in the trade, except patient number 1, who was on a disability pension.

Discussion

The follow-up of this small group of lithographers, aged 47 to 56 years, appears to confirm the earlier findings of an increased risk for malignant melanoma in the printing industry. The lithographers were skilled workers and long-term members of the same union. In all five cases occupational exposure had begun early in the study period. Selection bias, due to exclusion of workers who left the trade before 1974 because of exposure, was as-

*All but number 5 answered the questionnaire. Information on the trade for no 5 was obtained from the union.

sumed to be small but in any case would have tended to underestimate the risk. The overall cancer risk was as expected. Altogether, 10 cancers of the skin were observed.

Danish, English, and Swedish surveillance studies (2,3,7,8) have reported no increased risk for malignant melanoma in the printing industry or related trades. The industrial categories used in the studies may, however, have been too broad, resulting in an attenuation of the measured risk associated with work as a lithographer. In the printing industry in Sweden, an elevated risk of melanoma was found among printers (typographers), journalists, and editors (9).

We were unable to distinguish between the carcino- genic effects of the exposure to pigments, dyes, and organic solvents. We wish, however, to draw attention to hydroquinone, in view of its biological effect on melanocytes. Hydroquinone has been used in bleaching creams and resulted in temporary depigmenting, followed by ochronosis, collodion milium and damage to the melanocytes (10). It is presumed that hydroquinone interferes with the production of dopamine from dihydroxyphenylalanine (levodopa) and tyrosine. It is therefore interesting that the administration of levodopa to patients with Parkinson’s disease results in a relatively rapid recurrence of melanomas diagnosed and treated previously (11). Depigmentation of the skin has also been observed in photographers after the use of hydroquinone (12).

A high incidence among professional occupations in the printing industry may point to a life-style rather than to an occupational hazard (9). Increased risks for malignant melanoma have been observed in the pharmaceutical industry (13), in association with exposure to polychlorated biphenyls (14), vinyl chloride monomer (15) and soldering (16). Undoubtedly the risk for developing melanoma is multifactorial, sun exposure probably being the most important factor (17). Chemical compounds in combination with sun exposure may increase the risk for malignant melanoma among lithographers.
