Additional index words. daily germination rate, final germination percentage, pH

Abstract. Saline and alkaline conditions often coexist in nature. Unlike salinity that causes osmotic and ionic stresses, alkalinity reflects the impact of high pH on plant growth and development. In this research, seven turfgrass species, tall fescue (\textit{Festuca arundinacea Schreb.}), kentucky bluegrass (\textit{Poa pratensis} L.), creeping bentgrass (\textit{Agrostis stolonifera} L.), perennial ryegrass (\textit{Lolium perenne} L.), zoysia grass (\textit{Zoysia japonica} Steud.), bermudagrass [\textit{Cynodon dactylon} var. \textit{dactylon} (L.) Pers.], and alkaligrass [\textit{Puccinellia distans} (Jacq.) Parl.], were germinated under 10 saline–alkaline conditions (two salinity concentrations (25 and 50 mM) x five alkalinity levels (pH = 7.2, 8.4, 9.1, 10.0, 10.8)) in a controlled environment. Seed germination was evaluated based on final germination percentage and daily germination rate. Alkaligrass and kentucky bluegrass showed the highest and lowest germination under saline conditions, respectively. Limited variations in germination were observed in other species, except bermudagrass, which showed a low germination rate at 50 mM salinity. Alkalinity did not cause a significant effect on seed germination of tested turfgrass species.

High soil salinity is often problematic to turfgrass managers. Salinity causes osmotic stress (i.e., physiological drought), ion imbalance, and phytotoxicity and adversely affects plant growth and development (Qian and Harivandi, 2007), resulting in reduced visual quality and playability of the turfgrass. Many factors such as deficient precipitation, water percolation from high water tables, low-quality water (e.g., recycled water, well water, and salt water from sea water intrusion), and salts from fertilizers and deicer can result in high soil salinity (Wu and Lin, 1993). Various turfgrass species respond to soil salinity differently. For example, kentucky bluegrass is very sensitive to saline conditions, whereas creeping bentgrass shows moderate salinity sensitivity (Marcum, 2007). Tall fescue, perennial ryegrass, and zoysiagrass are moderately tolerant to salinity, whereas bermudagrass and alkaligrass are highly tolerant (Marcum, 2007).

Alkalinity (high pH) and salinity often coexist in nature, especially in sodic soils because of the hydrolysis of exchangeable sodium (Guerrero-Alves et al., 2002; Javid et al., 2011). Of the cultivated land worldwide (13.2 \times 10^9 ha), \(\approx 23\%\) is affected by salinity and another \(37\%\) is affected by sodicity (Läuchli and Lütteg, 2002). More than 70% land in northeast China is covered by alkaline meadow and it is expanding (Kawanabe and Zhu, 1991). High soil pH (greater than 8.5) has been reported on more than 80% of the sodic soils in Australia (Rengasamy, 2002). Qian and Mecham (2005) reported that an increase of soil salinity, sodium content, and pH on golf fairways was observed after long-term (4 to 33 years) use of recycled water.

Previous research on salinity stress has been focused on the impact of neutral salts such as NaCl on plant growth and development (Dai et al., 2009; Zhang et al., 2011). Recent studies have demonstrated that the combined saline-alkaline conditions are more detrimental to plants than salinity alone (Javid et al., 2012; Li et al., 2010; Liu and Shi, 2010; Paz et al., 2012; Shi and Wang, 2005). Lower seed germination was observed in sheepgrass [\textit{Leymus chinenensis} (Trin. Tzvel.), switchgrass (\textit{Panicum virgatum} L.), and wheat (\textit{Triticum aestivum} L.) under the combined saline–alkaline stress than salinity alone (Guo et al., 2010; Lin et al., 2014; Liu et al., 2014). Many seeds exposed to the combined saline–alkaline condition were not able to recover even after the stress was removed, suggesting that high pH may cause structural decomposition in seeds (Guo et al., 2010). Photosynthetic pigments, stomatal conductance, and net photosynthetic rates were significantly reduced in sunflower (\textit{Helianthus annuus} L.) under saline–alkaline conditions, but not saline stress alone (Liu and Shi, 2010). In addition to the salinity injuries, alkalinity under saline–alkaline conditions may inhibit iron absorption and cause precipitation of calcium, magnesium, and phosphorus, thus interrupting ion homeostasis in plant cells (Javid et al., 2012). A higher Na\textsuperscript{+}/K\textsuperscript{+} ratio was observed in various crops under the combined stress than salinity stress alone (Javid et al., 2012; Liu and Shi, 2010; Shi and Wang, 2005). Li et al. (2010) and Liu and Shi (2010) reported higher total organic acid production in plants under the combined saline–alkaline stress than the saline condition alone. Accumulation of organic acid contributes to osmotic adjustment under a stressful environment; however, it is energy-consuming resulting in reduced ability of ion regulation (Li et al., 2010; Liu and Shi, 2010). Furthermore, alkaline conditions may interfere with abscisic acid distribution between roots and the rhizosphere and its transportation within plant organs, resulting in root growth inhibition (Degenhardt et al., 2000; Javid et al., 2011).

To our knowledge, turfgrass responses to saline–alkaline conditions have not been evaluated. Therefore, this study was conducted to determine the effect of a saline–alkaline condition on turfgrass during seed germination, a critical period of turfgrass development and when plants are most likely to experience salt accumulation (Almansouri et al., 2001). Results will provide useful information to managers for selecting turfgrass species tolerant to saline–alkaline soil conditions and to breeders for screening and developing tolerant germplasms.

Materials and Methods

Seven turfgrass species were used in this experiment, including four commercially available cool-season turfgrasses (‘L-93’ creeping bentgrass, ‘Stonewall’ tall fescue, ‘Diva’ kentucky bluegrass, and ‘Zoom’ perennial ryegrass), one native cool-season grass (‘Salty’ alkaligrass), and two warm-season turfgrasses (‘Zenith’ zoysiagrass and ‘Rivera’ bermudagrass). These six commercial species are commonly used on golf courses, recreational areas, and residential home lawns, whereas the native species have shown good tolerance to both saline and alkaline conditions (Marcum, 2007; Turgeon, 1991) and high potential for turfgrass use under low maintenance (McKernan et al., 2001; Watkins et al., 2011).

Saline–alkaline conditions were simulated using neutral (NaCl and Na\textsubscript{2}SO\textsubscript{4}) and alkaline (Na\textsubscript{2}CO\textsubscript{3} and NaHCO\textsubscript{3}) salts following the method of Li et al. (2009). A total of 11 treatments were included: one control [deionized/distilled water (ddH\textsubscript{2}O), electrical conductivity (EC) = 0.1 dS m\textsuperscript{−1}, pH = 7.1] and a two (salinity level at 25 and 50 mM) \times five (pH level at 7.2, 8.4, 9.1, 10.0, and 10.8) factorial combination.

The seeds of each grass species were surface sterilized and germinated following the method of Zhang et al. (2011) with minor modifications. The seeds were submerged in 70% ethanol for 5 min followed by 2% (v/v) sodium hypochlorite solution for 20 min and then rinsed three times with ddH\textsubscript{2}O. Forty surface-sterilized seeds of each grass species were placed on seed germination paper (Anchor Paper Company, St. Paul, MN) in

\textsuperscript{1}To whom reprint requests should be addressed; e-mail qi.zhang1@ndsu.edu.
100 × 15-mm petri dishes. Before seed plating, the germination paper was moistened with 10 mL of ddH2O or salt solutions. Petri dishes were sealed with parafilm and placed in a culture room at 25 ± 2 °C under fluorescent light (36 μmol·s⁻¹·m⁻²) with a 16-h photoperiod.

The number of germinated seeds per dish was counted three times a week for 4 weeks. A seed was considered to be germinated when its emerged shoot was visible. Final germination percentage (FGP) and daily germination rate (DGR) were calculated following the method of Zhang et al. (2011) in which FGP (%) = 100 × (Sn/40) and DGR (%/d) = 100 × [Sn/(nD/40)], respectively, where n was the number of new seeds germinated at each counting and D was the number of days accumulated up to that counting. To provide an accurate indication of stress tolerance, data under saline–alkaline conditions were standardized as the percent germination of the control (Teolis et al., 2009). The increase in the ratio of stress to control was equated as an increase in tolerance.

The experiment was conducted as a seven (grass species) × two (salinity concentrations) × five (alkalinity levels) factorial design arranged in a randomized complete block design with three replicates (petri dishes). All data were subjected to analysis of generalized linear model (SAS Institute Inc., Cary, NC). Means were separated with Fisher’s protected least significant differences at P ≤ 0.05. The experiment was conducted twice (Study I and II). The two studies were homogeneous; therefore, data from Studies I and II were pooled for further analysis (data not shown).

**Results and Discussion**

*Salinity effects on turfgrass germination.*

An interaction between grass species and salinity level was detected in both FGP and DGR (Table 1). Alkaligrass showed the highest FGP, whereas kentucky bluegrass had the lowest FGP at 25 mM (Fig. 1). Zoysiagrass had a similar level of FGP as bermudagrass but was significantly higher than tall fescue, creeping bentgrass, and perennial ryegrass (average = 94.1% of the control). Similarly, alkaligrass and kentucky bluegrass were the most tolerant and the most sensitive to salinity, respectively at 50 mM. No significant difference in FGP was observed among zoysiagrass, tall fescue, creeping bentgrass, and perennial ryegrass at 50 mM (average = 83.7% of the control); however, bermudagrass had the second lowest FGP at this salinity level.

A similar trend was observed in DGR (Fig. 2). Alkaligrass and kentucky bluegrass had the highest and lowest DGR, respectively, under saline conditions. Bermudagrass had a similar level of DGR as zoysiagrass, tall fescue, creeping bentgrass, and perennial ryegrass at 25 mM; however, it had the second lowest DGR at 50 mM, which is similar to that of FGP.

This study clearly showed that alkaligrass is the most salinity-tolerant species of the five cool-season grasses tested followed by perennial ryegrass, tall fescue, and creeping bentgrass, whereas kentucky bluegrass is the most salinity-sensitive (Figs. 1 and 2). The results are consistent with previous findings (Dai et al., 2009; Zhang et al., 2011). Zoysiagrass had a similar level of FGP and DGR to tall fescue, perennial

**Fig. 1.** Final germination percentage of alkaligrass (AL), tall fescue (TF), perennial ryegrass (PR), creeping bentgrass (CB), kentucky bluegrass (KB), zoysiagrass (ZOY), and bermudagrass (BER) as affected by salinity. Data were expressed as percentage of the control (germination under deionized/distilled water) within each species. Means at each salinity level followed by the same letter were not significantly different at P ≤ 0.05.
ryegrass, and creeping bentgrass at both 25 and 50 mM in the present study (Figs. 1 and 2). In contrast, bermudagrass performed similarly to the aforementioned cool-season grasses only under low saline conditions (25 mM). As the salinity level reached 50 mM, bermudagrass had the second lowest FGP and DGR of the seven grasses evaluated (Figs. 1 and 2). Johnson et al. (2007) reported a similar germination of bermudagrass and zoysiagrass seeds under low salinity (3 dS m⁻¹ or less), consistent with findings of this study. In another experiment, however, seed germination rate of bermudagrass was significantly higher than kentucky bluegrass, tall fescue, and seashore paspalum (Paspalum vaginatum Schwartz) under saline conditions (EC = 0.6 to 600 mM). As the salinity level reached 50 mM, bermudagrass had the second lowest FGP and DGR of the seven grasses evaluated (Figs. 1 and 2). Johnson et al. (2007) reported a similar germination of bermudagrass and zoysiagrass seeds under low salinity (3 dS m⁻¹ or less), consistent with findings of this study. In another experiment, however, seed germination rate of bermudagrass was significantly higher than kentucky bluegrass, tall fescue, and seashore paspalum (Paspalum vaginatum Schwartz) under saline conditions (EC = 0.6 to 600 mM). Li et al. (2009) and Shi and Wang (2005); however, it was not observed in the present study. It was most likely the result of the higher salinity levels applied in the other studies (ranged from 60 to 600 mM) compared with our research (25 and 50 mM). Li et al. (2009) and Shi and Wang (2005) suggested that the effect of alkalinity was more pronounced under high salinity levels. Javid et al. (2012) reported that the salinity-sensitive Brassica juncea L. cultivar had lower plant biomass and tissue potassium, phosphorus, and iron content but higher sodium level than salinity-tolerant cultivars under salinity–alkaline stress. In the present study, turfgrass species contributed to more than 20% of the variation in seed germination (Table 1). Although no turfgrass × alkalinity interaction was observed, kentucky bluegrass, the most salinity-sensitive grass of the seven species tested in the present study, had decreased germination with an increase of alkalinity; no such trend was observed in the other grasses that have moderate or high salinity tolerance (data not shown). It suggests that salinity level needs to be adjusted according to the salinity tolerance of different plant materials used when the effects of alkalinity and salinity–alkaline conditions in future research are explored.

Alkalinity (pH) effects on turfgrass germination. Alkalinity did not influence FGP or DGR in the present study (Table 1). Our results indicate that salinity plays a more important role than alkalinity under the combined stress because salinity and alkalinity accounted for ≈10% and 1% of variation in seed germination, respectively (Table 1). Research on the effects of saline–alkaline stress on Aneurolepidium Chinese (Trin.) Kitag., Spartina alterniflora L., and switchgrass (Panicum virgatum L.) shows a similar finding that salinity is the dominant factor under saline–alkaline stress (Li et al., 2010; Liu et al., 2014; Shi and Wang, 2005). Severe damage caused by the combined saline–alkaline stress has been reported in other research (Li et al., 2010; Liu et al., 2014; Shi and Wang, 2005); however, it was not observed in the present study. It was most likely the result of the higher salinity levels applied in the other studies (ranged from 60 to 600 mM) compared with our research (25 and 50 mM). Li et al. (2009) and Shi and Wang (2005) suggested that the effect of alkalinity was more pronounced under high salinity levels. Javid et al. (2012) reported that the salinity-sensitive Brassica juncea L. cultivar had lower plant biomass and tissue potassium, phosphorus, and iron content but higher sodium level than salinity-tolerant cultivars under salinity–alkaline stress. In the present study, turfgrass species contributed to more than 20% of the variation in seed germination (Table 1). Although no turfgrass × alkalinity interaction was observed, kentucky bluegrass, the most salinity-sensitive grass of the seven species tested in the present study, had decreased germination with an increase of alkalinity; no such trend was observed in the other grasses that have moderate or high salinity tolerance (data not shown). It suggests that salinity level needs to be adjusted according to the salinity tolerance of different plant materials used when the effects of alkalinity and salinity–alkaline conditions in future research are explored.
