Intravascular lobular capillary hemangioma of the temporal artery

Jordan M. W. Fakoory, MBBS, Alan L. Smith, DM (Cardiovascular Surgery), and Nadia Depeiza, DM (Pathology) Bridgetown and Cave Hill, Barbados; and Mona, Jamaica

ABSTRACT

Lobular capillary hemangiomas (LCHs) are a common form of benign vascular tumors originating from the skin and subcutaneous tissues. We have described the case of a 47-year-old man who had presented with a 1-month history of a tender swelling to the right temporal region. Biopsy was performed to rule out temporal arteritis and demonstrated a subset of LCH, now formally known as intravascular LCH. We have described the occurrence of a rare subtype of LCH arising from the intravascular wall of the temporal artery. To the best of our knowledge, this is the only reported case of an intravascular LCH in the Caribbean. (J Vasc Surg Cases Innov Tech 2022;8:237-9.)

CASE REPORT

A 47-year-old man was referred by his general practitioner because of the results from a right temporal artery biopsy performed to rule out temporal arteritis. He had developed a swelling to the right side of the forehead 1 month before his presentation. He had no history of trauma, and he denied any other symptoms. The swelling had not increased in size since its initial presentation. He had a history of hypertension and paroxysmal atrial fibrillation but no history of embolic phenomena. The patient provided written informed consent for the report of his case details and imaging studies.

Vascular ultrasound revealed thrombosis of the right temporal artery (Fig 1). The physical examination was significant only for a 2-cm-long by 6-mm-wide soft, nontender swelling to the right temporal region, along the course of the temporal artery, which was palpable proximally and distally to the swelling. The patient underwent biopsy of the swelling, with excision of the 2-cm affected segment of the right temporal artery under local anesthesia, using an incision along the course of the artery, and was subsequently discharged.

Gross pathologic sectioning of the specimen revealed multiple pieces of tan-gray tissue (Fig 2). Microscopic examination of hematoxylin-eosin-stained sections exhibited a nodular vascular lesion composed of small capillaries arranged in a lobular fashion, and the specimen was diagnosed as an intravascular LCH (Fig 3). The blood investigation results, including measurement of inflammatory markers such as C-reactive protein and the erythrocyte sedimentation rate, were normal. Immunohistochemistry demonstrated strong cytoplasmic positivity for CD31, CD34, and factor VIII.
DISCUSSION

In 1979, a case series by Cooper et al. became the first to officially provide information on a rare subset of these LCHs arising from the vascular lumen of 18 patients. Now formally recognized by the International Society for the Study of Vascular Anomalies as intravascular LCHs (IVLCHs), they represent a very rare entity in the differential diagnosis of vascular pathology, as is evidenced by the paucity of literature surrounding their occurrence.

A total of 64 documented cases have been reported since their discovery in 1979. Of these 64 cases, 62 referred to lesions originating from the venous system and 2 referred to lesions arising from an arterial wall.

In 2020, Blaya et al. described the occurrence of an IVLCH arising from the superior vena cava of a 30-year-old woman. One decade earlier, Maher had described a similar occurrence arising from the right external jugular vein of a 41-year-old woman. Six years later, in 2016, Matsuzaki et al. described an acute presentation of severe right upper extremity edema in a 73-year-old man that was subsequently determined to have resulted from an obstruction to the right subclavian vein secondary to an IVLCH.

Although previous studies have reported vascular tumors arising from the temporal artery, the occurrence of an IVLCH arising within this region has remained a clinical rarity. In 1994, Margo et al. reported the case of a 27-year-old man who had presented acutely with a tender nodule to the right temporal region, a familiar clinical presentation concerning for temporal arteritis. However, the results from the biopsy provided evidence, not only for the occurrence of a temporal IVLCH, but, more strikingly, also an IVLCH arising from an arterial wall.

To the best of our knowledge, the present case represents only the second occurrence of a temporal IVLCH. More importantly, it encapsulates both an unusual location for vascular tumors and an unusual differential diagnosis regarding temporal artery pathology in general.

Historically, the presence of LCHs has been associated with preexisting cases of trauma, viruses, medications, arteriovenous malformations, and cytogenetic abnormalities. We have described the case of a 47-year-old man with hypertension, paroxysmal atrial fibrillation, and an acute tender swelling to the right temporal region. However, our patient reported no significant antecedent events. In addition, similar to the case reported by Margo et al. in 1994, our case illustrates a challenging clinical presentation because the historical and physical features both proved to be more suggestive of an inflammatory phenomenon than a neoplastic process.

The use of imaging in the diagnostic workup of these swellings, specifically ultrasound, has, in the past, proved to be useful but deceptive, with histopathologic examination the only real method of arriving at a definitive diagnosis. Nevertheless, the ultrasound features remained consistent with previously documented cases and are suggestive of an IVLCH. Intralesional vascularity will typically discern IVLCH from thrombosis, with regions of poor echogenicity seen amidst a homogeneous background. In addition to vascular ultrasound, various imaging modalities have proved beneficial in the diagnostic workup.

Previous reports have outlined the use of magnetic resonance venography as a valuable diagnostic tool. However, regardless of whether the features are consistent with thrombus or tumor, surgical resection remains the treatment of choice. The use of imaging in the diagnostic workup of these swellings, specifically ultrasound, has, in the past, proved to be useful but deceptive, with histopathologic examination the only real method of arriving at a definitive diagnosis. IVLCHs and their development are not known to be associated with thrombosis; however, there are recognized forms of vascular tumors that do share a temporal relationship. Intravascular papillary endothelial hyperplasia, often referred to as a Masson tumor, have historically been suspected to arise from thrombus resolution. Similarly, only one case of a Masson tumor has been previously documented, which originated from the temporal artery of a 75-year-old man in the setting of a suspected superficial temporal artery aneurysm.9 Nevertheless, our case has provided additional evidence regarding an important, albeit rare, entity for the differential diagnosis surrounding temporal artery pathology and, hence, reinforces the need to consider LCHs in the differential diagnosis of superficial swellings. At present, our case represents the only reported presentation of its kind in Barbados and the Caribbean.
