Responsive Emulsions for Sequential Multienzyme Cascades

Zhiyong Sun*, Qingcai Zhao*, Rainer Haag, and Changzhu Wu*

Abstract: Multienzyme cascade biocatalysis is an efficient synthetic process, avoiding the isolation/purification of intermediates and shifting the reaction equilibrium to the product side. However, multienzyme systems are often limited by their incompatibility and cross-reactivity. Herein, we report a multi-responsive emulsion to proceed multienzyme reactions sequentially for high reactivity. The emulsion is achieved using a CO₂, pH, and thermo-responsive block copolymer as a stabilizer, allowing the on-demand control of emulsion morphology and phase composition. Applying this system to a three-step cascade reaction enables the individual optimal condition for each enzyme, and a high overall conversion (ca. 97% of the calculated limit) is thereby obtained. Moreover, the multi-responsiveness of the emulsion allows the facile and separate yielding/recycling of products, polymers and active enzymes. Besides, the system could be scaled up with a good yield.

Enzymes, the biologic catalysts from nature, have achieved enormous success in modern chemical and pharmaceutical industries. In particular, they are increasingly explored for single-step reactions including oxidation, reduction, and isomerization. However, in nature, cells do not just employ single reactions alone but combine them for essential metabolic pathways, e.g., tricarboxylic acid cycle. This natural design has initiated great efforts in bioinspired multienzyme reactions, e.g., one-pot cascades, to avoid the isolation of intermediates and overcome unfavorable reaction equilibrium, significantly saving time and production costs.

However, operating multiple enzymes in abiological conditions often suffers from some intractable limitations. The first limitation, namely, incompatibility issue, stems from the fact that different enzymes often have different optimal reaction conditions, e.g., pH, temperature and co-factors, and therefore cannot be simply combined in one system. The second issue is the cross-reactivity, which occurs when one enzyme accepts not only its substrates but also the intermediates/products in the whole cascade route, eventually leading to undesired side reactions.

An elegant solution to the above issues is to compartmentalize multienzyme reactions in spatially different domains of one system. Emulsions, the dispersion of one liquid phase within a second immiscible liquid, seem to be a good choice, because they provide not only a large interfacial area for fast reactions but also heterogeneous phases to host different reactions. These benefits, especially their large interface, have promoted rapidly the field of “emulsion biocatalysis” to address a wide range of synthetic challenges to date. For instance, microemulsions, mini-emulsions, and Pickering emulsions were employed to encapsulate enzymes for the single-step enantioselective reduction, hydrolysis, and esterification. Recently, we further advanced the field by developing multi-compartmentalized emulsion biocatalysis for benzoic condensation and carbonyl reduction. In principle, polymeric emulsions are attractive because polymers are easily controlled for desirable application properties in addition to good recyclability. An example of such controllability is that polymeric emulsions can be made responsive to diverse external stimuli, e.g., pH, temperature, CO₂, magnetic field and light. This stimuli responsiveness allowed the controllable emulsification and demulsification, which were successfully explored for oil recovery and chemocatalysis. However, until now, stimuli-responsive emulsions for biocatalysis have been relatively underdeveloped and to the best of our knowledge, they have never been explored for multienzyme cascades despite their potential to improve reaction compatibility and reduce cross-reactivity.

Herein, we present a scalable multi-responsive emulsion as controllable liquid scaffolds to proceed efficient multienzyme cascades. A pH-, CO₂-, and thermo-responsive polymeric emulsion is obtained by utilizing a diblock copolymer, poly(N-[2-(dibutylamino)ethyl]acrylamide)-b-poly(N-isopropylacrylamide) (PDBAEAM-b-PNIPAm), as the stabilizer. This multi-responsiveness allows not only switching the biocatalysis on/off by on-demand emulsification/demulsification, but also the control of phase composition in the demulsified status (Scheme 1). As a result, the exchange of enzymes and a facile yet high conversion of biocatalysis can be achieved by applying different stimuli. Furthermore, utilizing this system in a sequential approach, each...
biocatalytic step undergoes under its optimal condition, and therefore, the performance of the multienzyme reactions can be improved without incompatibility and cross-reactivity issues.

To design the multi-responsive block copolymer, we opted to use PNIPAm and PDBAEAM as the temperature- and pH/CO2-responsive segments because of their biocompatibility to enzymes$^{[25]}$ and orthogonal responsiveness in different stimuli state.$^{[26]}$ Moreover, due to their characteristic molecular structures, the hydrophilic PNIPAm and hydrophobic PDBAEAM can be respectively switched to the hydrophobic and hydrophilic segment in response to environmental changes,$^{[27]}$ thus allowing the precise control of the hydrophobicity of the block copolymer for multi-responsive emulsions. The block copolymer was synthesized by reversible addition-fragmentation chain-transfer polymerization (see ESI), and the ratio of PDBAEAM/PNIPAm was obtained again by handshaking. The reversibility of emulsification/demulsification was demonstrated by repeating the heating/cooling and CO2/N2 cycles. Besides CO2 and temperature, the emulsion was also responsive to pH changing, but at pH 6. In lower pH conditions, the whole diblock copolymer became hydrophilic and therefore cannot work as an emulsifier. The thermal stability of the emulsion was investigated at the temperature from 20 to 40°C (Figure 1d). When the temperature was lower than 25°C, the emulsion was stable for more than 12 h (Figure S2). At 30°C, slight phase separation was observed over 12 h. At 35°C, the emulsion was stable for about 3 hours, while at 40°C the emulsification was unsuccessful, which was due to the change of PNIPAm block from hydrophobic to hydrophilic over LCST.

To investigate the responsiveness of the emulsion, temperature change and CO2/N2 treatment were applied, respectively (Figure 1e). Demulsification could be achieved by two methods via, for example, keeping the emulsion at 40°C or bubbling CO2 to the emulsion for 10 minutes. Although in both cases demulsification was achieved, the location of the polymer was different, which was confirmed by the yellowish color of the toluene or water phase, respectively. After the demulsification, the system could not be emulsified anymore by shaking, thus suggesting the change of the block copolymer amphiphilicity. However, after cooling down the system to room temperature or bubbling N2, the emulsion could be obtained again by handshaking. The reversibility of emulsification/demulsification was demonstrated by repeating the heating/cooling and CO2/N2 cycles. Besides CO2 and temperature, the emulsion was also responsive to pH changing (Figure S3).

Three different enzymes, Candida antarctica Lipase B (CalB), thermophilic alcohol dehydrogenase (ADH-ht)$^{[28]}$ and benzaldehyde lyase (BAL)$^{[29]}$ were obtained (see ESI) to study their catalytic performance in a 1 mL emulsion, where 2.5 mg mL$^{-1}$ enzymes and 200 mM substrates residues in aqueous and organic phases, respectively. Three reactions, hydrolysis of acetic acid benzyl ester (AABE), oxidation of benzyl alcohol (BeOH), and benzoin condensation, were performed individually under their optimal pH conditions in
the emulsion (Figures S5–7), using a biphasic system as a control. Product concentration was determined by GC measurements using an external standard method.\[30\] Figure 2a showed that our emulsion system largely improved the catalytic efficiency of all reactions compared to the biphasic control due to its large interfacial area. Furthermore, the responsive emulsion contributed to facilitated purification. Most traditional emulsifiers end up in final product, bringing additional difficulty in product purification.\[31\] Even though some polymeric stabilizers can be precipitated from emulsions,\[14a\] it is usually at cost of using a large amount of antisolvents. Here, we showed the demulsification by CO\(_2\) treatment, the obtained colorless organic phase (Figure S4) contained no polymers and was sent directly for the follow-up workup. Besides, the facile separation contributed to a higher conversion than the direct precipitation process (Figure 2a) because precipitation could lead to a small amount of product embedded in the polymer sediments. The demulsification, however, offered clear phase separation and the entire product was in the organic phase and not wasted. Therefore, the responsive emulsion provided an easy, economical (less solvent needed) method with the high bioconversion. The final conversion of the biocatalytic reactions was about 95% (hydrolysis by CalB), 80% (oxidation by ADH-ht), and 40% (benzoin condensation by BAL), respectively.

Next, the influence of demulsification on enzymes and their reusability was investigated. Circular dichroism (CD) spectrum (Figure 2b) showed negligible changes in enzyme secondary structure after demulsification by both CO\(_2\) treatment and heating. This positive result encouraged us to perform 20 cycles of emulsification/demulsification, in which the enzyme activity in emulsion and demulsified status was compared. In the case of demulsification by CO\(_2\) (Figure 2c), the activity of both CalB and ADH-ht had an only slight decrease, while BAL lost 30% and 50% activity after the first and second round and finally retained 45% after 20 cycles. This was because the introduction of CO\(_2\) lowered the pH value of the system, which demoted BAL performance. On the other hand, when using temperature change to run the cycles (Figure S8), the activity of CalB and BAL decreased gradually after each circle, and finally reached 70% and 60% after 20 cycles, respectively. In comparison, as a thermophilic enzyme, ADH-ht was almost not influenced in the first 15 cycles and eventually retained more than 80% activity. These results suggested that the multi-responsiveness of our emulsion not only allowed for a facile recycling of products but also provided more opportunities for enzyme reuse under their favourable conditions.

The accomplishment of single enzyme reactions encouraged us to further investigate their cascade reaction (Figure 3a). To this end, initially, we were curious about whether our responsive emulsion would be useful for avoiding multi-enzyme cross-reactivity. Interestingly, no cross-reactivity could be observed in the one-pot cascade reaction (Figure S15), which may be either due to the substrate specificity of enzymes\[28a,32\] or because of side-products below our detection limit. However, one big challenge of this cascade was that the optimal condition for every step differed largely from each other (Figures S16–18). For example, CalB and ADH-ht preferred higher temperatures, while BAL was only stable at the temperature from 20 to 30°C (Figure S18). Considering that the polymeric emulsion was not stable at
high temperature, 30°C was, therefore, set for the one-pot cascade reaction in further studies. In addition to the temperature, pH also had a great influence on all enzymatic performance (Figure S19). The three-step cascade reaction was carried out under both pH 6 and 8 for 24 hours. In the pH 6 experiment (Figure S20), the first step of hydrolysis by CalB was fast and almost fully completed. However, due to the low activity of both ADH-ht and BAL under an acidic condition, the production of benzaldehyde (25 mM) and benzoin was largely limited (4.6 mM, overall conversion 9%). In comparison, in the case of one-pot cascade at pH 8 (Figure 3b), although the first step was slower, the latter two steps were carried out under suitable pH and were able to shift the reaction equilibrium. Eventually, the overall conversion was higher (5.6 mM, overall conversion 11%).

To improve the overall catalytic efficiency, the above three-step reaction was then performed in a sequential fashion and operated separately under the individual optimal pH and temperature conditions of the corresponding enzyme, which was achieved by the stepwise heating to allow on-demand phase separation for changing enzyme solution from one to another (Scheme 1). Initially, every single biotransformation was carried out for 8 hours. Figure 3c showed the concentration change of substrates, intermediates, and final products. AABE was hydrolyzed rapidly by CalB, and after 8 hours, about 65% was converted to BeOH. CalB was then replaced by ADH-ht for the following oxidation reaction. In the next 8 hours, more than half of BeOH was consumed to produce about 40 mM benzaldehyde. Demulsification and exchange of the enzyme were then performed again to introduce BAL for benzoin condensation. In the last 8 hours, 7.3 mM benzoin was obtained as the final product (single-step conversion near 35%). The final conversion in this sequential cascade approach was slightly higher than that of 24-hour one-pot cascade experiments, and it was 15%.

In order to further improve the reaction conversion, we provided enough reaction time to each step of the cascade. Specifically, the first-step reaction was conducted for 20 hours, while the second and third steps were operated under suitable pH and were able to shift the reaction equilibrium. Eventually, the overall conversion was higher (5.6 mM, overall conversion 11%).
