Inclusive search for supersymmetry using razor variables in pp collisions at $\sqrt{s} = 13$ TeV

The CMS Collaboration

Abstract

An inclusive search for supersymmetry using razor variables is performed in events with four or more jets and no more than one lepton. The results are based on a sample of proton-proton collisions corresponding to an integrated luminosity of 2.3 fb$^{-1}$ collected with the CMS experiment at a center-of-mass energy of $\sqrt{s} = 13$ TeV. No significant excess over the background prediction is observed in data, and 95% confidence level exclusion limits are placed on the masses of new heavy particles in a variety of simplified models. Assuming that pair-produced gluinos decay only via three-body processes involving third-generation quarks plus a neutralino, and that the neutralino is the lightest supersymmetric particle with a mass of 200 GeV, gluino masses below 1.6 TeV are excluded for any branching fractions for the individual gluino decay modes. For some specific decay mode scenarios, gluino masses up to 1.65 TeV are excluded. For decays to first- and second-generation quarks and a neutralino with a mass of 200 GeV, gluinos with masses up to 1.4 TeV are excluded. Pair production of top squarks decaying to a top quark and a neutralino with a mass of 100 GeV is excluded for top squark masses up to 750 GeV.

Submitted to Physical Review D
1 Introduction

Supersymmetry (SUSY) is a proposed extended spacetime symmetry that introduces a bosonic (fermionic) partner for every fermion (boson) in the standard model (SM) [1–9]. Supersymmetric extensions of the SM are particularly compelling because they yield solutions to the gauge hierarchy problem without the need for large fine tuning of fundamental parameters [10–15], exhibit gauge coupling unification [16–21], and can provide weakly interacting particle candidates for dark matter [22, 23]. For SUSY to provide a “natural” solution to the gauge hierarchy problem, the three Higgsinos, two neutral and one charged, are expected to be light, and two top squarks, one bottom squark, and the gluino must have masses below a few TeV, making them potentially accessible at the CERN LHC. Previous searches for SUSY by the CMS [24–30] and ATLAS [31–37] Collaborations have probed SUSY particle masses near the TeV scale, and the increase in the center-of-mass energy of the LHC from 8 to 13 TeV provides an opportunity to significantly extend the sensitivity to higher SUSY particle masses [38–51]. In R-parity conserving SUSY scenarios, the lightest SUSY particle (LSP) is stable and assumed to be weakly interacting. For many of these models, the experimental signatures at the LHC are characterized by an abundance of jets and a large transverse momentum imbalance, but the exact form of the final state can vary significantly, depending on the values of the unconstrained model parameters. To ensure sensitivity to a broad range of SUSY parameter space, we adopt an inclusive search strategy, categorizing events according to the number of identified leptons and b-tagged jets. The razor kinematic variables \( M_R \) and \( R^2 \) [53, 54] are used as search variables and are generically sensitive to pair production of massive particles with subsequent direct or cascading decays to weakly interacting stable particles. Searches for SUSY and other beyond the SM phenomena using razor variables have been performed by both the CMS [53–58] and ATLAS [59, 60] Collaborations in the past. We interpret the results of the inclusive search using simplified SUSY scenarios for pair production of gluinos and top squarks. First, we consider models in which the gluino undergoes three-body decay, either to a bottom or top quark-antiquark pair and the lightest neutralino \( \tilde{\chi}_0^1 \), assumed to be the lightest SUSY particle; or to a bottom quark (antiquark), a top antiquark (quark), and the lightest chargino \( \tilde{\chi}_\pm^1 \), assumed to be the next-to-lightest SUSY particle (NLSP). The NLSP is assumed to have a mass that is 5 GeV larger than the mass of the LSP, motivated by the fact that in many natural SUSY scenarios the lightest chargino and the two lightest neutralinos are Higgsino-like and quasi-degenerate [61]. The NLSP decays to an LSP and an off-shell W boson, whose decay products mostly have too low momentum to be identifiable. The specific choice of the NLSP-LSP mass splitting does not have a large impact on the results of the interpretation. The full range of branching fractions to the three possible decay modes (\( b\bar{b}\tilde{\chi}_0^1 \), \( b\tilde{t}\tilde{\chi}_\pm^1 \), or \( \tilde{t}\tilde{\chi}_0^1 \)) is considered, assuming that these sum to 100%. We also consider a model in which the gluino decays to a first- or second-generation quark-antiquark pair and the LSP. Finally, we consider top squark pair production with the top squark decaying to a top quark and the LSP. Diagrams of these simplified model processes are shown in Fig. 1. This paper is organized as follows. Section 2 presents an overview of the CMS detector. A description of simulated signal and background samples is given in Section 3. Section 4 describes physics object reconstruction and the event selection. Section 5 describes the analysis strategy and razor variables, and the background estimation techniques used in this analysis are described in Section 6. Section 7 covers the systematic uncertainties. Finally, our results and their interpretation are presented in Section 8 followed by a summary in Section 9.
Simulated Monte Carlo (MC) samples are used for modeling of the SM backgrounds in the search regions and for calculating the selection efficiencies for SUSY signal models. The production of t\(t\)+jets, W+jets, Z+jets, \(\gamma\)+jets, and QCD multijet events, as well as production of gluino and top squark pairs, is simulated with the MC generator MADGRAPH v5 [63]. Single top quark events are modeled at next-to-leading order (NLO) with MADGRAPH_aMC@NLO v2.2 [64] for the s-channel, and with POWHEG v2 [65, 66] for the t-channel and W-associated production. Contributions from t\(t\)W, t\(t\)Z are also simulated with MADGRAPH_aMC@NLO v2.2. Simulated events are interfaced with PYTHIA v8.2 [67] for fragmentation and parton show-
ering. The NNPDF3.0LO and NNPDF3.0NLO [68] parton distribution functions (PDF) are used, respectively, with MadGraph, and with Powheg and MadGraph+AMC@NLO. The SM background events are simulated using a Geant4-based model [69] of the CMS detector. The simulation of SUSY signal model events is performed using the CMS fast simulation package [70]. All simulated events include the effects of pileup, i.e. multiple pp collisions within the same or neighboring bunch crossings, and are processed with the same chain of reconstruction programs as is used for collision data. Simulated events are weighted to reproduce the observed distribution of pileup vertices in the data set, calculated based on the measured instantaneous luminosity. The SUSY signal production cross sections are calculated to next-to-leading order (NLO) plus next-to-leading-logarithm (NLL) accuracy [71–76], assuming all SUSY particles other than those in the relevant diagram to be too heavy to participate in the interaction. The NLO+NLL cross section and its associated uncertainty [76] are used to derive the exclusion limit on the masses of the SUSY particles. The hard scattering was generated with MadGraph up to two extra partons to model initial-state radiation at the matrix element level, and simulated events were interfaced to Pythia for the showering, fragmentation and hadronization steps.

4 Object reconstruction and selection

Physics objects are defined using the particle-flow (PF) algorithm [77, 78]. The PF algorithm reconstructs and identifies each individual particle with an optimized combination of information from the various elements of the CMS detector. All reconstructed PF candidates are clustered into jets using the anti-kt algorithm [79, 80] with a distance parameter of 0.4. The jet momentum is determined as the vector sum of all particle momenta in the jet, and jet-energy corrections are derived from simulation and confirmed by in-situ measurements of the energy balance in dijet and photon+jet events. Jets are required to pass loose identification criteria on the jet composition designed to reject spurious signals arising from noise and failures in the event reconstruction [81, 82]. For this search, we consider jets with transverse momentum \( p_T > 40 \text{ GeV} \) and \( |\eta| < 3.0 \). The missing transverse momentum vector \( \vec{p}_T^{\text{miss}} \) is defined as the projection on the plane perpendicular to the beams of the negative vector sum of the momenta of all reconstructed PF candidates in an event. Its magnitude is referred to as the missing transverse energy \( E_T^{\text{miss}} \). Electrons are reconstructed by associating a cluster of energy deposited in the ECAL with a reconstructed track [83], and are required to have \( p_T > 5 \text{ GeV} \) and \( |\eta| < 2.5 \). A “tight” selection used to identify prompt electrons is based on requirements on the electromagnetic shower shape, the geometric matching of the track to the calorimeter cluster, the track quality and impact parameter, and isolation. The isolation of electrons and muons is defined as the scalar sum of the transverse momenta of all neutral and charged PF candidates within a cone \( \Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} \) along the lepton direction. The variable is corrected for the effects of pileup using an effective area correction [84], and the cone size \( \Delta R \) shrinks with increasing lepton \( p_T \) according to

\[
\Delta R = \begin{cases} 
0.2, & p_T \leq 50 \text{ GeV} \\
10 \text{ GeV} / p_T, & 50 < p_T \leq 200 \text{ GeV} \\
0.05, & p_T > 200 \text{ GeV}.
\end{cases}
\]

The use of the lepton \( p_T \) dependent isolation cone enhances the efficiency for identifying leptons in events containing a large amount of hadronic energy, such as those with tt production. For tight electrons, the isolation is required to be less than 10% of the electron \( p_T \). The selection efficiency for tight electrons increases from 60% for \( p_T \) around 20 GeV to 70% for \( p_T \) around
40 GeV and to 80% for $p_T$ above 50 GeV. To improve the purity of all-hadronic signals in the zero-lepton event categories, a looser “veto” selection is also defined. For this selection, electrons are required to have $p_T > 5$ GeV. The output of a boosted decision tree is used to identify electrons based on shower shape and track information \[83\]. For electrons with $p_T > 20$ GeV, the isolation is required to be less than 20% of the electron $p_T$. For electrons with $p_T$ between 5 and 20 GeV, the value of the isolation, computed by summing the $p_T$’s of all particle flow candidates within a $\Delta R$ cone of 0.3, is required to be less than 5 GeV. For the veto electron selection, the efficiency increases from 60% for $p_T$ around 5 GeV to 80% for $p_T$ around 15 GeV and 90% for $p_T$ above 20 GeV. Muons are reconstructed by combining tracks found in the muon system with corresponding tracks in the silicon detectors \[85\], and are required to have $p_T > 5$ GeV and $|\eta| < 2.4$. Muons are identified based on the quality of the track fit, the number of detector hits used in the tracking algorithm, and the compatibility between track segments. As for electrons, we define “tight” and “veto” muon selections. The absolute value of the 3D impact parameter significance of the muon track, which is defined as the ratio of the impact parameter to its estimated uncertainty, is required to be less than 4. For both tight and veto muons with $p_T > 20$ GeV the isolation is required to be less than 20% of the muon $p_T$, while for veto muons with $p_T$ between 5 and 20 GeV the isolation computed using a $\Delta R$ cone of 0.4 is required to be less than 10 GeV. For tight muons we require $d_0 < 0.2$ cm, where $d_0$ is the transverse impact parameter of the muon track, while this selection is not applied for veto muons. The selection efficiency for tight muons increases from 65% for $p_T$ around 20 GeV to 75% for $p_T$ around 40 GeV and to 80% for $p_T$ above 50 GeV. For the veto muon selection, the efficiency increases from 85% for $p_T$ around 5 GeV to 95% for $p_T$ above 20 GeV. We additionally reconstruct and identify hadronically decaying $\tau$ leptons ($\tau_h$) to further enhance the all-hadronic purity of the zero-lepton event categories, using the hadron-plus-strips algorithm \[86\], which identifies $\tau$ decay modes with one charged hadron and up to two neutral pions, or three charged hadrons. The $\tau_h$ candidate is required to have $p_T > 20$ GeV, and the isolation, defined as the $p_T$ sum of other nearby PF candidates, must be below a certain threshold. The loose cutoff-based selection \[86\] is used and results in an efficiency of about 50% for successfully reconstructed $\tau_h$ decays. To identify jets originating from $b$-hadron decays, we use the combined secondary vertex $b$ jet tagger, which uses the inclusive vertex finder to select $b$ jets \[87, 88\]. The “medium” working point is used to define the event categories for the search signal regions, and for jets with $p_T$ between 40 and 200 GeV yields an efficiency of approximately 70% for $b$ jets and an average misidentification probability of 1.5% for jets originating from light-flavor quarks or gluons in typical background events relevant for this search. Photon candidates are reconstructed from clusters of energy deposits in the ECAL. They are identified using selections on the transverse shower width $\sigma_{\eta\eta}$ as defined in Ref. \[89\], and the hadronic to electromagnetic energy ratio ($H/E$). Photon isolation, defined as the scalar $p_T$ sum of charged particles within a cone of $\Delta R < 0.3$, must be less than 2.5 GeV. Finally, photon candidates that share the same energy cluster as an identified electron are vetoed.

5 Analysis strategy and event selection

We select events with four or more jets, using search categories defined by the number of leptons and $b$-tagged jets in the event. The Multijet category consists of events with no electrons or muons passing the tight or veto selection, and no selected $\tau_h$. Events in the one electron (muon) category, denoted as the Electron Multijet (Muon Multijet) category, are required to have one and only one electron (muon) passing the tight selection. Within these three event classes, we divide the events further into categories depending on whether the events have zero, one, two, or more than two $b$-tagged jets. Each event in the above categories is treated as a dijet-like event
by grouping selected leptons and jets in the event into two “megajets”, whose four-momenta are defined as the vector sum of the four-momenta of their constituent physics objects \cite{55}. The clustering algorithm selects the grouping that minimizes the sum of the squares of the invariant masses of the two megajets. We define the razor variables \( M_R \) and \( M_T^R \) as

\[
M_R \equiv \sqrt{(|\vec{p}_h^i| + |\vec{p}_l^i|)^2 - (p_T^h + p_T^l)^2},
\]

\[
M_T^R \equiv \sqrt{\frac{E_{\text{miss}}^i(p_T^h + p_T^l) - \vec{p}_{T i}^\text{miss} \cdot (\vec{p}_h^i + \vec{p}_l^i)}{2}},
\]

where \( \vec{p}_h^i, \vec{p}_l^i \) and \( p_T^h \) are the momenta of the \( i \)th megajet and its transverse and longitudinal components with respect to the beam axis, respectively. The dimensionless variable \( R \) is defined as

\[
R \equiv \frac{M_T^R}{M_R}.
\]

For a typical SUSY decay of a superpartner \( \tilde{q} \) decaying into an invisible neutralino \( \tilde{\chi}_1^0 \) and the standard model partner \( q \), the mass variable \( M_R \) peaks at a characteristic mass scale \cite{53,54} \( (m_Z^2 - m_{\tilde{\chi}_1^0}^2) / m_{\tilde{\chi}_1^0} \). For standard model background processes, the distribution of \( M_R \) has an exponentially falling shape. The variable \( R^2 \) is related to the missing transverse energy and is used to suppress QCD multijet background. The events of interest are triggered either by the presence of a high-\( p_T \) electron or muon, or through dedicated hadronic triggers requiring the presence of at least two highly energetic jets and with loose thresholds on the razor variables \( M_R \) and \( R^2 \). The single-electron (single-muon) triggers require at least one isolated electron and reach a plateau above 97% for \( p_T > 40 \) GeV. The efficiencies for the single electron trigger were measured in data and simulation and found to be in good agreement, as were the corresponding efficiencies for muons. Corrections for residual difference of trigger efficiency between data and MC simulation are applied to simulated samples. The hadronic razor trigger requires at least two jets with \( p_T > 80 \) GeV or at least four jets with \( p_T > 40 \) GeV. The events are also required to pass selections on the razor variables \( M_R > 200 \) GeV and \( R^2 > 0.09 \) and on the product \( (M_R + 300 \) GeV) \times (R^2 + 0.25) > 240 \) GeV. The efficiency of the hadronic razor trigger for events passing the baseline \( M_R \) and \( R^2 \) selections described below is 97% and is consistent with the prediction from MC simulation. For events in the Electron or Muon Multijet categories, the search region is defined by the selections \( M_R > 400 \) GeV and \( R^2 > 0.15 \). The \( p_T \) of the electron (muon) is required to be larger than 25 (20) GeV. To suppress backgrounds from the \( W(\ell\nu) + \text{jets} \) and \( tt \) processes, we require that the transverse mass \( M_T \) formed by the lepton momentum and \( \vec{p}_{T\text{miss}} \) be larger than 120 GeV. For events in the Multijet category, the search uses a region defined by the selections \( M_R > 500 \) GeV and \( R^2 > 0.25 \) and requires the presence of at least two jets with \( p_T > 80 \) GeV within \(|\eta| < 3.0\), for compatibility with the requirements imposed by the hadronic razor triggers. For QCD multijet background events, the \( E_{\text{T\text{miss}}} \) arises mainly from mismeasurement of the energy of one of the leading jets. In such cases, the two razor megajets tend to lie in a back-to-back configuration. Therefore, to suppress the QCD multijet background we require that the azimuthal angle \( \Delta \phi \) between the two razor megajets be less than 2.8 radians. Finally, events containing signatures consistent with beam-induced background or anomalous noise in the calorimeters are rejected using dedicated filters \cite{90,91}. 

6 Background modeling

The main background processes in the search regions considered are $W(\ell \nu)+$jets (with $\ell = e, \mu, \tau$), $Z(\nu \bar{\nu})+\text{jets}$, $t\bar{t}$, and QCD multijet production. For event categories with zero b-tagged jets, the background is primarily composed of the $W(\ell \nu)+$jets and $Z(\nu \bar{\nu})+\text{jets}$ processes, while for categories with two or more b-tagged jets it is dominated by the $t\bar{t}$ process. There are also very small contributions from the production of two or three electroweak bosons and from the production of $t\bar{t}$ in association with a $W$ or $Z$ boson. These contributions are summed and labeled “Other” in Fig. 25. We model the background using two independent methods based on control samples in data with entirely independent sets of systematic assumptions. The first method (A) is based on the use of dedicated control regions that isolate a specific background processes in order to control and correct the predictions of the MC simulation. The second method (B) is based on a fit to an assumed functional form for the shape of the observed data distribution in the two-dimensional $M_R$-$R^2$ plane. These two background predictions are compared and cross-checked against each other in order to significantly enhance the robustness of the background estimate.

6.1 Method A: simulation-assisted background prediction from data

The simulation-assisted method defines dedicated control regions that isolate each of the main background processes. Data in these control regions are used to control and correct the accuracy of the MC prediction for each of the background processes. Corrections for the jet energy response and lepton momentum response are applied to the MC, as are corrections for the trigger efficiency and the selection efficiency of electrons, muons, and b-tagged jets. Any disagreement observed in these control regions is then interpreted as an inaccuracy of the MC in predicting the hadronic recoil spectrum and jet multiplicity. Two alternative formulations of the method are typically used in searches for new physics [25, 30, 31]. In the first formulation, the data control region yields are extrapolated to the search regions via translation factors derived from simulation. In the second formulation, simulation to data correction factors are derived in bins of the razor variables $M_R$ and $R^2$ and are then applied to the simulation prediction of the search region yields. The two formulations are identical and the choice of which formulation is used depends primarily on the convenience of the given data processing sequence. In both cases, the contributions from background processes other than the one under study are subtracted using the MC prediction. We employ the first formulation of the method for the estimate of the QCD background, while the second formulation is used for modeling all other major backgrounds. Details of the control regions used for each of the dominant background processes are described in the subsections below. Finally, the small contribution from rare background processes such as $t\bar{t}Z$ is modeled using simulation. Systematic uncertainties on the cross sections of these processes are propagated to the final result.

6.1.1 The $t\bar{t}$ and $W(\ell \nu)+\text{jets}$ background

The control region to isolate the $t\bar{t}$ and $W(\ell \nu)+\text{jets}$ processes is defined by requiring at least one tight electron or muon. To suppress QCD multijet background, the quantities $E_T^{\text{miss}}$ and $M_T$ are both required to be larger than 30 GeV. To minimize contamination from potential SUSY processes and to explicitly separate the control region from the search regions, we require $M_T < 100$ GeV. The $t\bar{t}$ enhanced control region is defined by requiring that there be at least one b-tagged jet, and the $W(\ell \nu)+\text{jets}$ enhanced control region is defined by requiring no such b-tagged jets. Other than these b-tagged jet requirements, we place no explicit requirement on the number of jets in the event, in order to benefit from significantly larger control samples. We first derive corrections for the $t\bar{t}$ background, and then measure correc-
6.1 Method A: simulation-assisted background prediction from data

Figure 2: The $M_R$ distributions for events in the $t\bar{t}$ (left) and $W(\ell\nu) + jets$ (right) control regions are shown, comparing data with the MC prediction. The ratio of data to the background prediction is shown on the bottom panel, with the statistical uncertainty expressed through the data point error bars and the systematic uncertainty of the background prediction represented by the shaded region. In the right-hand plot, the $t\bar{t}$ MC events have been reweighted according to the corrections derived in the $t\bar{t}$-enhanced control region.

Corrections for the $W(\ell\nu) + jets$ process after first applying the corrections already obtained for the $t\bar{t}$ background in the $W(\ell\nu) + jets$ control region. As discussed above, the corrections to the MC prediction are derived in two-dimensional bins of the $M_R$-$R^2$ plane. We observe that the $M_R$ spectrum predicted by the simulation falls off less steeply than the control region data for both the $t\bar{t}$ and $W(\ell\nu) + jets$ processes, as shown in Fig. 2. In Fig. 3, we show the two-dimensional $M_R$-$R^2$ distributions for data and simulation in the $W(\ell\nu) + jets$ control region. The statistical uncertainties in the correction factors due to limited event yields in the control region bins are propagated and dominate the total uncertainty of the background prediction. For bins at large $M_R$ (near 1000 GeV), the statistical uncertainties range between 15% and 50%. Corrections to the MC simulation are first measured and applied as a function of $M_R$ and $R^2$, inclusively in the number of selected jets. As our search region requires a higher multiplicity of jets, an additional correction factor is required to accurately model the jet multiplicity. We measure this additional correction factor to be $0.90 \pm 0.03$ by comparing the data and the MC prediction in the $W(\ell\nu) + jets$ and $t\bar{t}$ control region for events with four or more jets. To control for possible simulation mismodeling that is correlated between the number of jets and the razor variables, we perform additional cross-checks of the $M_R$ and $R^2$ distributions in bins of the number of $b$-tagged jets in the $t\bar{t}$ and $W(\ell\nu) + jets$ control regions for events with four or more jets. For bins that show statistically significant disagreement, the size of the disagreement is propagated as a systematic uncertainty. The typical range of these additional systematic uncertainties is between 10% and 30%. The $t\bar{t}$ and $W(\ell\nu) + jets$ backgrounds in the zero-lepton Multijet event category are composed of events with at least one lepton in the final state, which is either out of acceptance or fails the veto electron, muon, or $\tau_\ell$ selection. Two additional control regions are defined in order to control the accuracy of the modeling of the acceptance and efficiency for selecting electrons or muons, and $\tau_\ell$. We require events in the veto lepton ($\tau_\ell$, candidate) control region to have at least one veto electron or muon ($\tau_\ell$, candidate) selected. The $M_T$ is required to be between 30 and 100 GeV in order to suppress QCD multijet background and contamination from potential new physics processes. At least two jets with $p_T > 80$ GeV and at least four jets with $p_T > 40$ GeV are required, consistent with the search region requirements. Finally, we consider events with $M_R > 400$ GeV and $R^2 > 0.25$. The distribution of the veto lepton $p_T$ for events in the veto lepton and veto $\tau_\ell$ control regions are shown in Fig. 4 and demonstrate that the MC models describe well the observed data. The observed discrepancies in any bin are propagated as systematic uncertainties in the prediction of the $t\bar{t}$ and $W(\ell\nu) + jets$ in the Multi-
Figure 3: The two-dimensional $M_R$-$R^2$ distribution for the $W(\ell\nu)$+jets enhanced (upper) and the $t\bar{t}$ dilepton (lower) control regions is shown, comparing data with the MC prediction. The $t\bar{t}$ MC events have been reweighted according to the correction factors derived in the $t\bar{t}$-enhanced control region. The two-dimensional $M_R$-$R^2$ distribution is shown in a one dimensional representation, with each $M_R$ bin marked by the dashed lines and labeled near the top, and each $R^2$ bin labeled below. The bottom panel shows the ratio of data to the background prediction, with uncertainties displayed as in Fig. 2.
jet category search region. The \(t\bar{t}\) background in the Electron and Muon Multijet categories is primarily from the dilepton decay mode as the \(M_T\) requirement highly suppresses the semi-leptonic decay mode. Corrections to the MC simulation derived from the \(t\bar{t}\) control region primarily arise from semi-leptonic decays. We define an additional control region enhanced in dilepton \(t\bar{t}\) decays to confirm that the MC corrections derived from a region dominated by semi-leptonic decays also apply to dilepton decays. We select events with two tight leptons, both with \(p_T > 30\, \text{GeV}, E_T^{\text{miss}} > 40\, \text{GeV}\), and dilepton mass larger than 20 GeV. For events with two leptons of the same flavor, we additionally veto events with a dilepton mass between 76 and 106 GeV in order to suppress background from \(Z\) boson decays. At least one b-tagged jet is required to enhance the purity for the \(t\bar{t}\) process. Finally, we mimic the phase space region similar to our search region in the Electron and Muon Multijet categories by treating one lepton as having failed the identification criteria and applying the \(M_T\) requirement using the other lepton. The correction factors measured in the \(t\bar{t}\) control region are applied to the MC prediction of the dilepton \(t\bar{t}\) cross-check region in bins of \(M_R\) and \(R^2\). In Fig. 3 we show the \(M_R\)-\(R^2\) distribution for the dilepton \(t\bar{t}\) cross-check region in events with four or more jets, and we observe no significant mismodeling by the simulation, indicating that the measured corrections are accurate.

6.1.2 The \(Z \rightarrow \nu \bar{\nu}\) background

Three independent control regions are used to predict the \(Z(\nu \bar{\nu}) + \text{jets}\) background, relying on the assumption that the hadronic recoil spectrum and the jet multiplicity distribution of the \(Z(\nu \bar{\nu}) + \text{jets}\) process are similar to those of the \(W(\ell \nu) + \text{jets}\) and \(\gamma + \text{jets}\) processes. The primary and most populated control region is the \(\gamma + \text{jets}\) control region, defined by selecting events with at least one photon passing loose identification and isolation requirements. The events are triggered using single-photon triggers, and the photon is required to have \(p_T > 50\, \text{GeV}\). The momentum of the photon candidate in the transverse plane is added vectorially to \(p_T^{\text{miss}}\) in order to simulate an invisible particle, as one would have in the case of a \(Z \rightarrow \nu \bar{\nu}\) decay, and the \(M_R\) and \(R^2\) variables are computed according to this invisible decay scenario. A template fit to the distribution of \(\sigma_{\eta\eta}\) is performed to determine the contribution from misidentified photons to the \(\gamma + \text{jets}\) control region and is found to be about 5%, independent of the \(M_R\) and \(R^2\). Events from the \(\gamma + \text{jets}\) process where the photon is produced within the cone of a jet (labeled as \(\gamma + \text{jets}\) fragmentation) are considered to be background and subtracted using the MC predic-
Background modeling

Figure 5: The one-dimensional distribution of \( M_R \) in the \( \gamma + \text{jets} \) control region (above) and the two-dimensional \( M_R-R^2 \) distribution in the \( \gamma + \text{jets} \) control region (below) are shown. The two-dimensional \( M_R-R^2 \) distribution is shown in a one-dimensional representation as in Fig. 3. The bottom panel shows the ratio of data to the background prediction, with uncertainties displayed as in Fig. 2.

Corrections for backgrounds from rarer processes such as \( W\gamma, Z\gamma, \) and \( t\bar{t}\gamma \) are also subtracted similarly. In Fig. 5 we show the \( M_R \) distribution as well as the two-dimensional \( M_R-R^2 \) distribution for the \( \gamma + \text{jets} \) control region, where we again observe a steeper \( M_R \) falloff in the data compared to the simulation. Correction factors are derived in bins of \( M_R \) and \( R^2 \) and applied to the MC prediction for the \( Z \rightarrow \nu\bar{\nu} \) background in the search region. The statistical uncertainties for the correction factors range between 10% and 30% and are among the dominant uncertainties for the \( Z \rightarrow \nu\bar{\nu} \) background prediction. Analogous to the procedure for the \( t\bar{t} \) and \( W(\ell\nu)+\text{jets} \) control region, we derive an additional correction factor of 0.87 ± 0.05 to accurately describe the yield in events with four or more jets. Additional cross-checks are performed in bins of the number of b-tagged jets and systematic uncertainties ranging from 4% for events with zero b-tagged jets to 58% for events with three or more b-tagged jets are derived. The second control region, enhanced in the \( W(\ell\nu)+\text{jets} \), is defined identically to the \( W(\ell\nu)+\text{jets} \) control region described in Section 6.1.1, except that the lepton is treated as invisible by adding its momentum vectorially to \( \vec{p}_T^{\text{miss}} \), and the \( M_R \) and \( R^2 \) variables are computed accordingly. Correction factors
are computed using events from this control region, and the difference between these correction factors and those computed from the $\gamma$+jets control region is propagated as a systematic uncertainty. These uncertainties range between 10% and 40% depending on the $M_{R^2}$ bin. The third control region, enhanced in $Z \rightarrow \ell^+\ell^-$ decays, is defined by selecting events with two tight electrons or two tight muons, and requiring that the dilepton mass is between 76 and 106 GeV. Events are required to have no b-tagged jets in order to suppress $t\bar{t}$ background. The two leptons are treated as invisible by adding their momenta vectorially to $\vec{p}_{T}^{miss}$. We apply the correction factors obtained from the $\gamma$+jet control region to the $Z \rightarrow \ell^+\ell^-$ MC prediction and perform a cross-check against data in this control region. No significant discrepancy between the data and the prediction is observed.

6.1.3 The QCD Multijet background

The QCD multijet processes contribute about 10% of the total background in the zero-lepton Multijet event category for bins with zero or one b-tagged jets. Such events enter the search regions in the tails of the $E_{T}^{miss}$ distribution when the energy of one of the jets in the event is significantly under- or over-measured. In most such situations, the $\vec{p}_{T}^{miss}$ points either toward or away from the leading jets and therefore the two megajets tend to be in a back-to-back configuration. The search region is defined by requiring that the azimuthal angle between the two megajets $\Delta \phi_{R}$ be less than 2.8, which was found to be an optimal selection based on studies of QCD multijet and signal simulated samples. We define the control region for the QCD background process to be events with $\Delta \phi_{R} > 2.8$, keeping all other selection requirements identical to those for the search region. The purity of the QCD multijet process in the control region is more than 70%. After subtracting the non-QCD background, we project the observed data yield in the control region to the search region using the translation factor $\zeta$:

$$\zeta = \frac{N(\Delta \phi_{R} < 2.8)}{N(\Delta \phi_{R} > 2.8)},$$

where the numerator and denominator are the number of events passing and failing the selection on $|\Delta \phi_{R}| < 2.8$, respectively. We find that the translation factor calculated from the MC simulation decreases as a function of $M_R$ and is, to a large degree, constant as a function of $R^2$. Using data events in the low $R^2$ region (0.15 to 0.25), dominated by QCD multijet background, we measure the translation factor $\zeta$ as a function of $M_R$ to cross-check the values obtained from the simulation. The $M_R$ dependence of $\zeta$ is modeled as the sum of a power law and a constant. This functional shape is fitted to the values of $\zeta$ calculated from the MC. A systematic uncertainty of 87% is propagated, covering both the spread around the fitted model as a function of $M_R$ and $R^2$ in simulation, and the difference between the values measured in simulation and data. The function used for $\zeta$ and the values measured in data and simulation are shown in Fig. 6. We perform two additional cross-checks on the accuracy of the MC prediction for $\zeta$ in control regions dominated by processes similar to the QCD multijet background with no invisible neutrinos in the final state. The first cross-check is performed on a dimuon control region enhanced in $Z \rightarrow \mu^+\mu^-$ decays, and the second cross-check is performed on a dijet control region enhanced in QCD dijet events. In both cases, the events at large $R^2$ result from cases similar to our search region where the energy of a leading jet is severely mismeasured. We compare the values of $\zeta$ measured in these data control regions to the values predicted by the simulation and observe an agreement at the 20% level, well within the systematic uncertainty of 87% assigned to the QCD background estimate.
Background modeling

The translation factor $\zeta$ is shown as a function of $M_R$. The curve shows the functional form used to model the $M_R$ dependence, and the open circle and black dot data points are the values of $\zeta$ measured in the low-$R^2$ data control region and the QCD MC simulation, respectively. The hashed region indicates the size of the systematic uncertainty in $\zeta$.

6.2 Method B: fit-based background prediction

The second background prediction method is based on a fit to the data with an assumed functional form for the shape of the background distribution in the $M_R$-$R^2$ plane. Based on past studies [54, 56], the shape of the background in the $M_R$ and $R^2$ variables is found to be well described by the following functional form:

$$f_{\text{SM}}(M_R, R^2) = \left[ b(M_R - M_R^0)^{1/n}(R^2 - R_0^2)^{1/n} - 1 \right] e^{-b(M_R - M_R^0)^{1/n}(R^2 - R_0^2)^{1/n}},$$

(6)

where $M_R^0$, $R_0^2$, $b$, and $n$ are free parameters. In the original study [54], this function with $n$ fixed to 1 was used to model the data in each category. The function choice was motivated by the observation that for $n = 1$, the function projects to an exponential both on $R^2$ and $M_R$, and $b$ is proportional to the exponential rate parameter in each one-dimensional projection. The generalized function in Eq. (6) was found to be in better agreement with the SM backgrounds over a larger range of $R^2$ and $M_R$ [56]. The two parameters $b$ and $n$ determine the tail of the distribution in the two-dimensional plane, while the $M_R^0$ ($R_0^2$) parameter affects the tail of the one-dimensional projection on $R^2$ ($M_R$). Background estimation is performed using an extended, binned, maximum likelihood fit to the $M_R$ and $R^2$ distribution in one of two ways:

- A fit to the data in the sideband regions in $M_R$ and $R^2$, defined more precisely below, as a model-independent way to look for excesses or discrepancies. The fit is performed using only the data in the sideband, and the functional form is extrapolated to the full $M_R$ and $R^2$ plane.
- A fit to the data in the full search region in $M_R$ and $R^2$ under background-only and signal-plus-background hypotheses, following a modified frequentist approach (LHC CLs) [92–96] to interpret the data in the context of particular SUSY simplified models.

The sideband region is defined to be 100 GeV in width in $M_R$ and 0.05 in $R^2$. Explicitly, for the Multijet event category, it comprises the region $500 \text{ GeV} < M_R < 600 \text{ GeV}$ and $0.3 < R^2 < 0.5$, plus the region $M_R > 500 \text{ GeV}$ and $0.25 < R^2 < 0.3$. For the Muon and Electron Multijet event categories, it comprises the region $400 \text{ GeV} < M_R < 500 \text{ GeV}$ and $0.2 < R^2 < 0.2$, plus the region $M_R > 400 \text{ GeV}$ and $0.15 < R^2 < 0.2$. For each event category, we fit the two-dimensional distribution of $M_R$ and $R^2$ in the sideband region using the above functional form, separately.
for events with zero, one, two, and three or more b-tagged jets. The normalization in each event category and each b-tagged jet bin is independently varied in the fit. Due to the lack of data events in the category with three or more b-tagged jets, we constrain the shape in this category to be related to the shape for events with two b-tagged jets as follows:

\[ f_{\geq 3b}^{SM}(M_R, R^2) = \left(1 + m_{MR}(M_R - M_{R^{offset}}) \right) f_{2b}^{SM}(M_R, R^2), \]

where \( f_{2b}^{SM}(M_R, R^2) \) and \( f_{\geq 3b}^{SM}(M_R, R^2) \) are the probability density functions for events with two and with three or more b-tagged jets, respectively; \( M_{R^{offset}} \) is the lowest \( M_R \) value in a particular event category; and \( m_{MR} \) is a floating parameter constrained by a Gaussian distribution centered at the value measured using the simulation and with a 100% uncertainty. The above form for the shape of the background events with three or more b-tagged jets is verified in simulation. Numerous tests are performed to establish the robustness of the fit model in adequately describing the underlying distributions. To demonstrate that the background model gives an accurate description of the background distributions, we construct a representative data set using MC samples, and perform the background fit using the form given by Eq. (6). Goodness of fit is evaluated by comparing the background prediction from the fit with the prediction from the simulation. This procedure is performed separately for each of the search categories and we find that the fit function yields an accurate representation of the background predicted by the simulation. We also observe that the fit model is insensitive to variations of the background composition predicted by the simulation in each event category by altering relative contributions of the dominant backgrounds, performing a new fit with the alternative background composition, and comparing the new fit results to the nominal fit result. The contributions of the main \( t\bar{t}, W(\ell\nu)+jets, \) and \( Z(\nu\bar{\nu}) \) backgrounds are varied by 30%, and the rare backgrounds from QCD multijet and \( t\bar{t}Z \) processes are varied by 100%. For the Muon and Electron Multijet event categories, we also vary the contributions from the dileptonic and semi-leptonic decays of the \( t\bar{t} \) background separately by 30%. In each of these tests, we observe that the chosen functional form can adequately describe the shapes of the \( M_R \) and \( R^2 \) distributions as predicted by the modified MC simulation. Additional pseudo-experiment studies are performed comparing the background prediction from the sideband fit and the full region fit to evaluate the average deviation between the two fit predictions. We observe that the sideband fit and the full region fit predictions in the signal-sensitive region differ by up to 15% and we propagate an additional systematic uncertainty to the sideband fit background prediction to cover this average difference. To illustrate method B, we present the data and fit-based background predictions in Fig. 7, for events in the 2 b-tag and \( \geq 3 \) b-tag Multijet categories. The number of events observed in data is compared to the prediction from the sideband fit in the \( M_R \) and \( R^2 \) bins. To quantify the agreement between the background model and the observation, we generate alternative sets of background shape parameters from the covariance matrix calculated by the fit. An ensemble of pseudo-experiment data sets is created, generating random \((M_R, R^2)\) pairs distributed according to each of these alternative shapes. For each \( M_R-R^2 \) bin, the distribution of the predicted yields from the ensemble of pseudo-experiments is compared to the observed yield in data. The agreement between the predicted and the observed yields is described as a two-sided \( p \)-value and translated into the corresponding number of standard deviations for a normal distribution. Positive (negative) significance indicates the observed yield is larger (smaller) than the predicted one. We find that the pattern of differences between data and background predictions in the different bins considered is consistent with statistical fluctuations. To demonstrate that the model-independent sideband fit procedure used in the analysis would be sensitive to the presence of a signal, we perform a signal injection test. We sample a signal-plus-background pseudo-data set and perform a background-only fit in the sideband. We show one illustrative example of such a test in Fig. 8, where we inject a signal
Figure 7: Comparison of the sideband fit background prediction with the observed data in bins of $M_R$ and $R^2$ variables in the Multijet category for the 2 b-tag (upper) and $\geq 3$ b-tag (lower) bins. Vertical dashed lines denote the boundaries of different $M_R$ bins. On the upper panels, the colored bands represent the systematic uncertainties in the background prediction, and the uncertainty bands for the sideband bins are shown in green. On the bottom panels, the deviations between the observed data and the background prediction are plotted in units of standard deviation ($\sigma$), taking into account both statistical and systematic uncertainties. The green and yellow horizontal bands show the boundaries of 1 and $2\sigma$. 
Figure 8: The result of the background-only fit performed in the sideband of the 2 b-tag (upper) and $\geq$3 b-tag (lower) bins of the Multijet category on a signal-plus-background pseudo-data set assuming a gluino pair production simplified model signal, where gluinos decay with a 100% branching fraction to a $b\bar{b}$ pair and the LSP, with $m_{\tilde{g}} = 1.4$ TeV and $m_{\chi^0_1} = 100$ GeV, at nominal signal strength. A detailed explanation of the figure format is given in the caption of Fig. 7.
corresponding to gluino pair production, in which each gluino decays to a neutralino and a $b\bar{b}$ pair with $m_{\tilde{g}} = 1.4$ TeV and $m_{\tilde{\chi}_1^0} = 100$ GeV. The deviations with respect to the fit predictions are shown for the 2 b-tag and $\geq 3$ b-tag Multijet categories. We observe characteristic patterns of excesses in two adjacent groups of bins neighboring in $M_R$.

6.3 Comparison of two methods

The background predictions obtained from methods A and B are systematically compared in all of the search region categories. For method B, the model-independent fit to the sideband is used for this comparison. In Fig. 9, we show the comparison of the two background predictions for two example event categories. The predictions from the two methods agree within the uncertainties of each method. The uncertainty from the fit-based method tends to be slightly larger at high $M_R$ and $R^2$ due to the additional uncertainty in the exact shape of the tail of the distribution, as the $n$ and $b$ parameters are not strongly constrained by the sideband data. The two background predictions use methods based on data that make very different systematic assumptions. Method A assumes that corrections to the simulation prediction measured in control regions apply also to the signal regions, while method B assumes that the shape of the background distribution in $M_R$ and $R^2$ is well described by a particular exponentially falling functional form. The agreement observed between predictions obtained using these two very different methods significantly enhances the confidence of the background modeling, and also validates the respective assumptions.

7 Systematic uncertainties

Various systematic uncertainties are considered in the evaluation of the signal and background predictions. Different types of systematic uncertainties are considered for the two different background models. For method A, the largest uncertainties arise from the precision with which the MC corrections are measured. The dominant uncertainties in the correction factors result from statistical uncertainties due to the limited size of the control region event sample. We also propagate systematic uncertainties in the theoretical cross-section for the small residual backgrounds present in the control regions, and they contribute 2–5% to the correction factor uncertainty. Additional systematic uncertainties are computed from the procedure that tests that the accuracy of the MC corrections as a function of $(M_R, R^2)$, and the number of $b$-tagged jets in events with four or more jets. The total uncertainty from this procedure ranges from 10% for the most populated bins to 50% and 100% for the least populated bins. For the $Z \rightarrow \nu\bar{\nu}$ process, we also propagate the difference in the correction factors measured in the three alternative control regions as a systematic uncertainty, intended to estimate the possible differences in the simulation mismodeling of the hadronic recoil for the $\gamma$+jets process and the $Z(\nu\bar{\nu})$+jets process. These systematic uncertainties range from 10 to 40%. For the QCD background prediction the statistical uncertainty due to limited event counts in the $\Delta\phi_R > 2.8$ control regions and the systematic uncertainty of 87% in the translation factor $\xi$ are propagated. For method B, the systematic uncertainties in the background are propagated as part of the maximum likelihood fit procedure. For each event category, the background shape in $M_R$ and $R^2$ is described by four independent parameters: two that control the exponential fall off and two that control the behavior of the nonexponential tail. Systematic uncertainties in the background are propagated through the profiling of these unconstrained shape parameters. For more populated bins, such as the 0 b-tag and 1 b-tag bins in the Multijet category, the systematic uncertainties range from about 30% at low $M_R$ and $R^2$ to about 70% at high $M_R$ and $R^2$. For sparsely populated bins such as the 3-or-more b-tag bin in the Muon Multijet or Electron Multijet categories, the systematic uncertainties range from about 60% at low $M_R$ and $R^2$ to more than 200% at high $M_R$ and $R^2$. 
Figure 9: Comparisons of the two alternative background predictions for the $M_R$-$R^2$ distribution for the 0 b-tag bin of the Multijet category (upper) and the 2 b-tag bin of the Muon Multijet category (lower). The two-dimensional $M_R$-$R^2$ distribution is shown in a one dimensional representation, with each $M_R$ bin marked by the dashed lines and labeled near the top and each $R^2$ bin labeled below. The ratios of the method B fit-based predictions to the method A simulation-assisted predictions are shown on the bottom panels. The method B uncertainty is represented by the error bars on the data points and the method A uncertainty is represented by the shaded region.
Table 1: Summary of the main instrumental and theoretical systematic uncertainties. The systematic uncertainty associated to the modeling of the initial-state radiation is only applied for events with recoil above 400 GeV.

| Source                        | Typical values [%] |
|-------------------------------|--------------------|
| Jet energy scale              | 2–15               |
| Electron energy scale         | 7–9                |
| Muon momentum scale           | 7–9                |
| Muon efficiency               | 7–8                |
| Electron efficiency           | 7–8                |
| Trigger efficiency            | 3                  |
| b-tagging efficiency          | 6–15               |
| b mistagging efficiency       | 4–7                |
| Missing higher orders         | 10–25              |
| Integrated luminosity         | 2.7                |
| Fast simulation corrections   | 0–10               |
| Initial-state radiation       | 15–30              |

Systematic uncertainties due to instrumental and theoretical effects are propagated as shape uncertainties in the signal predictions for methods A and B, and on the background predictions for method A. The background prediction from method B is not affected by these uncertainties as the shape and normalization are measured from data. Uncertainties in the trigger and lepton selection efficiency, and the integrated luminosity primarily affect the total normalization. Uncertainties in the b-tagging efficiency affect the relative yields between different b-tag categories. The uncertainties from missing higher-order corrections and the uncertainties in the jet energy and lepton momentum scale affect the shapes of the $M_R$ and $R^2$ distributions. For the signal predictions, we also propagate systematic uncertainties due to possible inaccuracies of the fast simulation in modeling the lepton selection and b tagging efficiencies. These uncertainties were evaluated by comparing the t$t$ and signal GEANT based MC samples with those that used fast simulation. Finally, we propagate an uncertainty in the modeling of initial-state radiation for signal predictions, that ranges from 15% for signal events with recoil between 400 and 600 GeV to 30% for events with recoil above 600 GeV. The systematic uncertainties and their typical impact on the background and signal predictions are summarized in Table 1.

8 Results and interpretations

We present results of the search using method A as it provides slightly better sensitivity. The two-dimensional $M_R$-$R^2$ distributions for the search regions in the Multijet, Electron Multijet, and Muon Multijet categories observed in data are shown in Figures 10–13 along with the background prediction from method A. We observe no statistically significant discrepancies and interpret the null search result using method A by determining the 95% confidence level (CL) upper limits on the production cross sections of the SUSY models presented in Section 1 using a global likelihood determined by combining the likelihoods of the different search boxes and sidebands. Following the LHC CL$_s$ procedure, we use the profile likelihood ratio test statistic and the asymptotic formula to evaluate the 95% CL observed and expected limits on the SUSY production cross section $\sigma$. Systematic uncertainties are taken into account by incor-
porating nuisance parameters \( \theta \), representing different sources of systematic uncertainty, into the likelihood function \( L(\sigma, \theta) \). For each signal model the simulated SUSY events are used to estimate the effect of possible signal contamination in the analysis control regions, and the method A background prediction is corrected accordingly. To determine a confidence interval for \( \sigma \), we construct the profile likelihood ratio test statistic 
\[-2 \ln \left( \frac{L(\sigma, \hat{\theta}_\sigma)}{L(\hat{\sigma}, \hat{\theta})} \right)\]
as a function of \( \sigma \), where \( \hat{\theta}_\sigma \) refers to the conditional maximum likelihood estimators of \( \theta \) assuming a given value \( \sigma \), and \( \hat{\sigma} \) and \( \hat{\theta} \) correspond to the global maximum of the likelihood. Then for example, a 68\% confidence interval for \( \sigma \) can be taken as the region for which the test statistic is less than 1. By allowing each nuisance parameter to vary, the test statistic curve is wider, reflecting the systematic uncertainty arising from each source, and resulting in a larger confidence interval for \( \sigma \). First, we consider the scenario of gluino pair production decaying to third-generation quarks. Gluino decays to the third-generation are enhanced if the masses of the third-generation squarks are significantly lighter than those of the first two generations, a scenario that is strongly motivated in natural SUSY models [61, 98–100]. Prompted by this, we consider the three decay modes:

- \( \tilde{g} \rightarrow b\bar{b}\tilde{\chi}_1^0 \);
- \( \tilde{g} \rightarrow t\bar{t}\tilde{\chi}_1^0 \);
- \( \tilde{g} \rightarrow b\bar{t}\tilde{\chi}_1^+ \rightarrow bW^+\tilde{\chi}_0^0 \) or charge conjugate,

where \( W^* \) denotes a virtual W boson. Due to a technical limitation inherent in the event generator, we consider these three decay modes for \( |m_{\tilde{g}} - m_{\tilde{\chi}_1^0}| \geq 225 \text{ GeV} \). For \( |m_{\tilde{g}} - m_{\tilde{\chi}_1^0}| < 225 \text{ GeV} \), we only consider the \( \tilde{g} \rightarrow b\bar{b}\tilde{\chi}_1^0 \) decay mode. The three-body gluino decays considered here capture all of the possible final states within this natural SUSY context including those of two-body gluino decays with intermediate top or bottom squarks. Past studies have shown that LHC searches exhibit a similar sensitivity to three-body and two-body gluino decays with a only a weak dependence on the intermediate squark mass [40]. We perform a scan over all possible branching fractions to these three decay modes and compute limits on the production cross section under each such scenario. The production cross section limits for a few characteristic branching fraction scan points are shown on the left of Fig. 16 as a function of the gluino and neutralino masses. We find a range of excluded regions for different branching fraction assumptions and generally observe the strongest limits for the \( \tilde{g} \rightarrow b\bar{b}\tilde{\chi}_1^0 \) decay mode over the full two-dimensional mass plane and the weakest limits for the \( \tilde{g} \rightarrow t\bar{t}\tilde{\chi}_1^0 \) decay mode. For scenarios that include the intermediate decay \( \tilde{\chi}_1^+ \rightarrow W^\pm\tilde{\chi}_0^0 \) and small values of \( m_{\tilde{\chi}_1^0} \), the sensitivity is reduced because the LSP carries very little momentum in both the NLSP rest frame and the laboratory frame, resulting in small values of \( E_T^{\text{miss}} \) and \( R^2 \). By considering the limits obtained for all scanned branching fractions, we calculate the exclusion limits valid for any assumption on the branching fractions, presented on the right of Fig. 16. For an LSP with mass of a few hundred GeV, we exclude pair production of gluinos decaying to third-generation quarks for mass below about 1.6 TeV. This result represents a unique attempt to obtain a branching fraction independent limit on gluino pair production at the LHC for the scenario in which gluino decays are dominated by three-body decays to third-generation quarks and a neutralino LSP. In Figure 17, we present additional interpretations for simplified model scenarios of interest. On the left, we show the production cross section limits on gluino pair production where the gluino decays to two light-flavored quarks and the LSP, and on the right we show the production cross section limits on top squark pair production where the top squark decays to a top quark and the LSP. For a very light LSP, we exclude top squark production with mass below 750 GeV.
Figure 10: The $M_R$-$R^2$ distribution observed in data is shown along with the background prediction obtained from method A for the Multijet event category in the 0 b-tag (upper) and 1 b-tag (lower) bins. The two-dimensional $M_R$-$R^2$ distribution is shown in a one-dimensional representation, with each $M_R$ bin marked by the dashed lines and labeled near the top, and each $R^2$ bin labeled below. The ratio of data to the background prediction is shown on the bottom panels, with the statistical uncertainty expressed through the data point error bars and the systematic uncertainty of the background prediction represented by the shaded region.
Figure 11: The $M_R$-$R^2$ distribution observed in data is shown along with the background prediction obtained from method A for the Multijet event category in the 2 b-tag (upper) and $\geq 3$ b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. 10.
Figure 12: The $M_R$-$R^2$ distribution observed in data is shown along with the background prediction obtained from method A for the Muon Multijet event category in the 0 b-tag (upper) and 1 b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. [10].
Figure 13: The $M_R$-$R^2$ distribution observed in data is shown along with the background prediction obtained from method A for the Muon Multijet event category in the 2 b-tag (upper) and $\geq$3 b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. 10.
Figure 14: The $M_R$-$R^2$ distribution observed in data is shown along with the background prediction obtained from method A for the Electron Multijet event category in the 0 b-tag (upper) and 1 b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. 10.
Figure 15: The $M_R$-R$^2$ distribution observed in data is shown along with the background prediction obtained from method A for the Electron Multijet event category in the 2 b-tag (upper) and $\geq 3$ b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. [10].
Figure 16: (Left) the expected and observed 95% confidence level (CL) upper limits on the production cross section for gluino pair production decaying to third-generation quarks under various assumptions of the branching fractions. The two gray dashed diagonal lines correspond to \(|m_{\tilde{g}} - m_{\tilde{\chi}^0_1}| = 25\) GeV, which is where the scan ends for the \(g \rightarrow b\tilde{\chi}^0_1 \tilde{\chi}^0_1\) decay mode, and \(|m_{\tilde{g}} - m_{\tilde{\chi}^0_1}| = 225\) GeV, which is where the scan ends for the remaining modes due to a technical limitation inherent in the event generator. For \(|m_{\tilde{g}} - m_{\tilde{\chi}^0_1}| < 225\) GeV, we only consider the \(g \rightarrow b\tilde{\chi}^0_1 \tilde{\chi}^0_1\) decay mode. (Right) the analogous upper limits on the gluino pair production cross section valid for any values of the gluino decay branching fractions.

Figure 17: Expected and observed 95% confidence level (CL) upper limits on the production cross section for (left) gluino pair production decaying to two light-flavored quarks and the LSP and (right) top squark pair production decaying to a top quark and the LSP. The white diagonal band in the right plot corresponds to the region \(|m_{\tilde{t}} - m_{\tilde{\chi}^0_1}| < 25\) GeV, where the signal efficiency is a strong function of \(m_{\tilde{t}} - m_{\tilde{\chi}^0_1}\), and as a result the precise determination of the cross section upper limit is uncertain because of the finite granularity of the available MC samples in this region of the \((m_{\tilde{t}}, m_{\tilde{\chi}^0_1})\) plane.
9 Summary

We have presented an inclusive search for supersymmetry in events with no more than one lepton, a large multiplicity of energetic jets, and missing transverse energy. The search is sensitive to a broad range of SUSY scenarios including pair production of gluinos and top squarks. The event categorization in the number of leptons and the number of b-tagged jets enhances the search sensitivity for a variety of different SUSY signal scenarios. Two alternative background estimation methods are presented, both based on transfer factors between data control regions and the search regions, but having very different systematic assumptions: one relying on the simulation and associated corrections derived in the control regions, and the other relying on the accuracy of an assumed functional form for the shape of background distribution in the \( M_R \) and \( R^2 \) variables. The two predictions agree within their uncertainties, thereby demonstrating the robustness of the background modeling. No significant deviations from the predicted standard model background are observed in any of the search regions, and this result is interpreted in the context of simplified models of gluino or top squark pair production. For decays to a top quark and an LSP with a mass of 100 GeV, we exclude top squarks with masses below 750 GeV. Considering separately the decays to bottom quarks and the LSP or first- and second-generation quarks and the LSP, gluino masses up to 1.65 TeV or 1.4 TeV are excluded, respectively. Furthermore, this search goes beyond the existing simplified model paradigm by interpreting results in a broader context inspired by natural SUSY, with multiple gluino decay modes considered simultaneously. By scanning over all possible branching fractions for three-body gluino decays to third generation quarks, exclusion limits are derived on gluino pair production that are valid for any values of the gluino decay branching fractions. For a chargino NLSP nearly degenerate in mass with the LSP and LSP masses in the range between 200 and 600 GeV, we exclude gluinos with mass below 1.55 to 1.6 TeV, regardless of their decays. This result is a more generic constraint on gluino production than previously reported at the LHC.

Acknowledgments

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: the Austrian Federal Ministry of Science, Research and Economy and the Austrian Science Fund; the Belgian Fonds de la Recherche Scientifique, and Fonds voor Wetenschappelijk Onderzoek; the Brazilian Funding Agencies (CNPq, CAPES, FAPERJ, and FAPESP); the Bulgarian Ministry of Education and Science; CERN; the Chinese Academy of Sciences, Ministry of Science and Technology, and National Natural Science Foundation of China; the Colombian Funding Agency (COLCIENCIAS); the Croatian Ministry of Science, Education and Sport, and the Croatian Science Foundation; the Research Promotion Foundation, Cyprus; the Secretariat for Higher Education, Science, Technology and Innovation, Ecuador; the Ministry of Education and Research, Estonian Research Council via IUT23-4 and IUT23-6 and European Regional Development Fund, Estonia; the Academy of Finland, Finnish Ministry of Education and Culture, and Helsinki Institute of Physics; the Institut National de Physique Nucléaire et de Physique des Particules / CNRS, and Commissariat à l’Énergie Atomique et aux Énergies Alternatives / CEA, France; the Bundes-
Individuals have received support from the Marie-Curie program and the European Research Council and EPLANET (European Union); the Leventis Foundation; the A. P. Sloan Foundation; the Alexander von Humboldt Foundation; the Belgian Federal Science Policy Office; the Fonds pour la Formation à la Recherche dans l’Industrie et dans l’Agriculture (FRIA-Belgium); the Agentschap voor Innovatie door Wetenschap en Technologie (IWT-Belgium); the Ministry of Education, Youth and Sports (MEYS) of the Czech Republic; the Council of Science and Industrial Research, India; the HOMING PLUS program of the Foundation for Polish Science, cofinanced from European Union, Regional Development Fund, the Mobility Plus program of the Ministry of Science and Higher Education, the National Science Center (Poland), contracts Harmonia 2014/14/M/ST2/00428, Opus 2013/11/B/ST2/04202, 2014/13/B/ST2/02543 and 2014/15/B/ST2/03998, Sonata-bis 2012/07/E/ST2/01406; the Thalis and Aristeia programs cofinanced by EU-ESF and the Greek NSRF; the National Priorities Research Program by Qatar National Research Fund; the Programa Clarín-COFUND del Principado de Asturias; the Rachadapisek Sompot Fund for Postdoctoral Fellowship, Chulalongkorn University and the Chulalongkorn Academic into Its 2nd Century Project Advancement Project (Thailand); and the Welch Foundation, contract C-1845.

A Results of method B fit-based background prediction

In Section 6.2, we detail the fit-based background prediction methodology and present the model-independent SUSY search results in the 2 b-tag and ≥3 b-tag bins of the Multijet category in Fig. 7. In Figs. 18-22 in this Appendix, we present the results of the search for SUSY signal events in the remaining categories, namely the 0 b-tag and 1 b-tag bins of the Multijet, the Muon Multijet, and Electron Multijet categories. No statistically significant deviations from the expected background predictions are observed in these categories in data.

![Multijet 0 b-tag sideband fit](image1)

![Multijet 1 b-tag sideband fit](image2)

Figure 18: Comparison of the predicted background with the observed data in bins of \( M_R \) and \( R^2 \) variables in the Multijet category for the 0 b-tag (upper) and 1 b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. 7.
Figure 19: Comparison of the predicted background with the observed data in bins of $M_R$ and $R^2$ variables in the Muon Multijet category for the 0 b-tag (upper) and 1 b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. [7].
Figure 20: Comparison of the predicted background with the observed data in bins of $M_R$ and $R^2$ variables in the Muon Multijet category for the 2 b-tag (upper) and $\geq$3 b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. 7.
Figure 21: Comparison of the predicted background with the observed data in bins of $M_R$ and $R^2$ variables in the Electron Multijet category for the 0 b-tag (upper) and 1 b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. 7.
Figure 22: Comparison of the predicted background with the observed data in bins of $M_R$ and $R^2$ variables in the Electron Multijet category for the 2 b-tag (upper) and $\geq$3 b-tag (lower) bins. A detailed explanation of the panels is given in the caption of Fig. [7]

†: Deceased
1: Also at Vienna University of Technology, Vienna, Austria
2: Also at State Key Laboratory of Nuclear Physics and Technology, Peking University, Beijing, China
3: Also at Institut Pluridisciplinaire Hubert Curien, Université de Strasbourg, Université de Haute Alsace Mulhouse, CNRS/IN2P3, Strasbourg, France
4: Also at Universidade Estadual de Campinas, Campinas, Brazil
5: Also at Universidade Federal de Pelotas, Pelotas, Brazil
6: Also at Université Libre de Bruxelles, Bruxelles, Belgium
7: Also at Deutsches Elektronen-Synchrotron, Hamburg, Germany
8: Also at Joint Institute for Nuclear Research, Dubna, Russia
9: Also at Suez University, Suez, Egypt
10: Now at British University in Egypt, Cairo, Egypt
11: Also at Ain Shams University, Cairo, Egypt
12: Now at Helwan University, Cairo, Egypt
13: Also at Université de Haute Alsace, Mulhouse, France
14: Also at CERN, European Organization for Nuclear Research, Geneva, Switzerland
15: Also at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia
16: Also at Tbilisi State University, Tbilisi, Georgia
17: Also at RWTH Aachen University, III. Physikalisches Institut A, Aachen, Germany
18: Also at University of Hamburg, Hamburg, Germany
19: Also at Brandenburg University of Technology, Cottbus, Germany
20: Also at Institute of Nuclear Research ATOMKI, Debrecen, Hungary
21: Also at MTA-ELTE Lendület CMS Particle and Nuclear Physics Group, Eötvös Loránd University, Budapest, Hungary
22: Also at University of Debrecen, Debrecen, Hungary
23: Also at Indian Institute of Science Education and Research, Bhopal, India
24: Also at Institute of Physics, Bhubaneswar, India
25: Also at University of Visva-Bharati, Santiniketan, India
26: Also at University of Ruhuna, Matara, Sri Lanka
27: Also at Isfahan University of Technology, Isfahan, Iran
28: Also at University of Tehran, Department of Engineering Science, Tehran, Iran
29: Also at Yazd University, Yazd, Iran
30: Also at Plasma Physics Research Center, Science and Research Branch, Islamic Azad University, Tehran, Iran
31: Also at Università degli Studi di Siena, Siena, Italy
32: Also at Purdue University, West Lafayette, USA
33: Also at International Islamic University of Malaysia, Kuala Lumpur, Malaysia
34: Also at Malaysian Nuclear Agency, MOSTI, Kajang, Malaysia
35: Also at Consejo Nacional de Ciencia y Tecnología, Mexico city, Mexico
36: Also at Warsaw University of Technology, Institute of Electronic Systems, Warsaw, Poland
37: Also at Institute for Nuclear Research, Moscow, Russia
38: Now at National Research Nuclear University ‘Moscow Engineering Physics Institute’ (MEPhI), Moscow, Russia
39: Also at St. Petersburg State Polytechnical University, St. Petersburg, Russia
40: Also at University of Florida, Gainesville, USA
41: Also at P.N. Lebedev Physical Institute, Moscow, Russia
42: Also at California Institute of Technology, Pasadena, USA
43: Also at Budker Institute of Nuclear Physics, Novosibirsk, Russia
44: Also at Faculty of Physics, University of Belgrade, Belgrade, Serbia
45: Also at INFN Sezione di Roma; Università di Roma, Roma, Italy
46: Also at Scuola Normale e Sezione dell’INFN, Pisa, Italy
47: Also at National and Kapodistrian University of Athens, Athens, Greece
48: Also at Riga Technical University, Riga, Latvia
49: Also at Institute for Theoretical and Experimental Physics, Moscow, Russia
50: Also at Albert Einstein Center for Fundamental Physics, Bern, Switzerland
51: Also at Gaziosmanpasa University, Tokat, Turkey
52: Also at Adiyaman University, Adiyaman, Turkey
53: Also at Mersin University, Mersin, Turkey
54: Also at Cag University, Mersin, Turkey
55: Also at Piri Reis University, Istanbul, Turkey
56: Also at Ozyegin University, Istanbul, Turkey
57: Also at Izmir Institute of Technology, Izmir, Turkey
58: Also at Marmara University, Istanbul, Turkey
59: Also at Kafkas University, Kars, Turkey
60: Also at Istanbul Bilgi University, Istanbul, Turkey
61: Also at Yildiz Technical University, Istanbul, Turkey
62: Also at Hacettepe University, Ankara, Turkey
63: Also at Rutherford Appleton Laboratory, Didcot, United Kingdom
64: Also at School of Physics and Astronomy, University of Southampton, Southampton, United Kingdom
65: Also at Instituto de Astrofísica de Canarias, La Laguna, Spain
66: Also at Utah Valley University, Orem, USA
67: Also at University of Belgrade, Faculty of Physics and Vinca Institute of Nuclear Sciences, Belgrade, Serbia
68: Also at Facoltà Ingegneria, Università di Roma, Roma, Italy
69: Also at Argonne National Laboratory, Argonne, USA
70: Also at Erzincan University, Erzincan, Turkey
71: Also at Mimar Sinan University, Istanbul, Istanbul, Turkey
72: Also at Texas A&M University at Qatar, Doha, Qatar
73: Also at Kyungpook National University, Daegu, Korea
