CASE REPORT

Cowden Syndrome with a Novel PTEN Mutation Presenting with Partial Epilepsy Related to Focal Cortical Dysplasia

Tadashi Adachi, Hiroshi Takigawa, Takashi Nomura, Yasuhiro Watanabe and Hisanori Kowa

Abstract:

Cowden syndrome is a rare autosomal dominant disorder characterized by multiple hamartomas of the ectoderm and brain. A 36-year-old Japanese man presented with right facial seizure during sleep and was admitted to our hospital. He showed cobblestoning over the tongue and palmar pitting but no neurological abnormalities while he was not having a seizure. Brain magnetic resonance imaging showed focal cortical dysplasia in the left frontal lobe. Electroencephalography showed sharp waves over the left frontal lesion. A genetic analysis revealed a novel mutation of PTEN. The administration of carbamazepine ended the seizures. This is the first Japanese case of Cowden syndrome with a novel PTEN gene mutation and cortical dysplasia.

Key words: Cowden syndrome, cortical dysplasia, PTEN, epilepsy

Introduction

Cowden syndrome is a rare disorder caused by autosomal dominant mutations in the phosphatase and tensin homologue on chromosome 10 (PTEN) tumor suppressor gene. Cowden syndrome is characterized by multiple hamartomas, particularly of the skin and gastrointestinal system, and is frequently associated with breast, thyroid, and genitourinary malignancies (1). In a study of 20 patients with Cowden syndrome, 7 (35%) had abnormalities on brain magnetic resonance imaging (MRI), which included dysplastic cerebellar gangliocytomas, meningiomas, and vascular malformations (2). However, cerebral cortical dysplasia is a rare manifestation of Cowden syndrome. We herein report a Japanese patient with Cowden syndrome who had cerebral cortical dysplasia, seizures, and a novel PTEN mutation.

Case Report

A 36-year-old man suffered a right facial seizure during sleep. The seizure awakened him and lasted for a few minutes. Three months later, he experienced another right facial seizure during a nap. He reported that this seizure also lasted for a few minutes, and then he lost consciousness. When he regained consciousness, he found vomitus near his pillow and experienced weakness of his right upper and lower limbs for about half a day. After eight days, he was admitted to our hospital. He had no family history of epilepsy or neurological disorders, but his father died of hepatocellular carcinoma. His birth and growth were normal, and he had no history of epilepsy or febrile convulsions, but he noticed bilateral palmar pitting as a teenager. His general condition was good, and his vital signs were within normal limits. He showed macrocephaly, and a skin examination revealed cobblestoning over the cheek and tongue (Fig. 1) and palmar pitting. He showed no neurological abnormalities during his time without seizures and no cognitive decline, aphasia, or apraxia, and he achieved a full score on the Mini-Mental State Examination. Blood tests for autoantibodies, amino acids, lactate, pyruvate, pituitary hormone, tumor markers, and infectious agents showed no abnormalities. An examination of the cerebrospinal fluid revealed normal pressure, no pleocytosis, a protein level of 30 mg/dL, and an IgG index of 0.370; in addition, myelin basic protein was within normal limits, and oligoclonal bands and culture and cytology were negative.

Brain MRI showed left frontal focal cortical dysplasia without contrast enhancement and linear T2 hyperintensities of the subcortical white matter (Fig. 2). Positron Emission...
Tomography-Computed Tomography showed hypometabolism of cortical dysplasia, and Single photon emission computed tomography showed hypoperfusion in this area (Fig. 2). Electroencephalography during wakefulness and sleep showed sharp waves from the left frontal lesion, along with convulsions during sleep. Sensory evoked potentials (SEPs) showed no cortical delay, laterality, or giant SEPs, and ¹⁸⁷⁶Ga scintigraphy showed no abnormal accumulation. A whole-body CT scan showed no hamartomas, even in the thyroid, breast, lung, and liver. Gastrointestinal endoscopy revealed multiple polyps.

We obtained written informed consent for genetic testing but did not provide genetic counseling because the patient refused it. All nine exons and exon-intron junctions of the PTEN gene were analyzed by polymerase chain reaction direct sequencing. A mutational analysis of PTEN showed a heterozygous deletion in exon 5 (c.486delC, Fig. 3). This mutation generally induces pathogenicity causing Cowden syndrome because of a leading stop codon. The patient was diagnosed with Cowden syndrome with a novel PTEN mutation and secondary epilepsy due to cortical dysplasia. He was administered carbamazepine, and the convulsions during sleep disappeared.

Figure 1. Skin abnormalities in our patient. A skin examination revealed cobblestoning over the cheek (A) and tongue (B).

Figure 2. Brain MRI images and PET-CT fusion images. The left frontal lobe showed cortical thickening (A; arrow) and linear subcortical T2 hyperintensities (B; arrow) with hypometabolism in this area (C; arrow).

Figure 3. A mutation analysis of PTEN showed a heterozygous deletion in exon 5 (c.486delC).
Cowden syndrome was first described by Lloyd and Dennis in 1963 and is characterized by macrocephaly, mucocutaneous lesions, acral keratosis, papillomatous papules, and a high risk of developing cancer in the breast, thyroid, and endometrium. This rare autosomal dominant disease has an estimated prevalence of 1 in 100,000 to 250,000 with genetic identification. In 1996, the International Cowden Consortium identified germline PTEN mutations as a cause of Cowden syndrome. PTEN is a tumor suppressor gene that encodes a key lipid phosphatase in the phosphoinositide 3-kinase signaling cascade and in cell proliferation and migration.

Cowden syndrome represents a late-onset phenotype of the PTEN mutation. Early presentations of PTEN mutations include Lhermitte-Duclos disease (dyplastic gangliocytomas in cerebellum), Bannayan-Riley-Ruvalcaba syndrome, and autism spectrum disorder with macrocephaly. An MRI study showed dyplastic gangliocytomas in the cerebellum, meningiomas, and vascular malformations as common abnormalities, occurring in 35% of patients with Cowden syndrome. The underlying etiology of these brain hamartomas is currently unknown. Several cases of Cowden syndrome with cortical dysplasia in childhood have been reported; however, only one case of adult-onset Cowden syndrome with cortical dysplasia has been published.

Recently, PTEN mutations have been found to play an important role in cancer and epilepsy, and PI3/Akt/mTOR inhibitors are being investigated as potential treatments. In a mouse model of cortical dysplasia, the PI3/Akt/mTOR inhibitor rapamycin reduced the tumor size and suppressed epileptic discharge and cortical hyperplasia. Furthermore, somatic mutations in the mechanistic target of rapamycin (MTOR) gene also cause focal cortical dysplasia. This evidence suggests that the PI3/Akt/mTOR pathway is closely related to the development of cortical dysplasia. We do not know why cortical dysplasia was present in our patient, but it may have slowly led to the development of his epilepsy in adulthood.

Cowden syndrome is an important differential diagnosis of adult-onset partial epilepsy with cortical dysplasia, and neurologists must check dermatological lesions, hamartomas, and malignant cancers and conduct a gene analysis in such patients.

The authors state that they have no Conflict of Interest (COI).
