2Department of Animal Science, Korea National Agricultural College, Hwaseong 445-760, Korea

Primary testicular tumors are the most common causes of cancer in male dogs. Overall, the majority of canine patients should be cured by testicular surgery. However, tumor markers are not well-known in veterinary medicine. We sought to determine using immunohistochemistry whether the combined human testicular tumor markers (placental alkaline phosphatase, OCT3/4, CD30, alpha-fetoprotein, inhibin-alpha, vimentin, c-KIT, and desmin) are expressed in canine seminomas and Sertoli cell tumors (SCTs). We examined 35 canine testicular tumors, 20 seminomas and 15 SCTs. c-KIT was expressed markedly in canine seminomas. Both inhibin-alpha and vimentin were expressed significantly in canine SCTs. The results of this study demonstrate differences and similarities between tumor marker expression of testicular tumors in dogs and humans. All the main markers in current routine use are discussed as well as potential useful markers for benign and malignant tumors, and tumor progression.

Keywords: dog, immunohistochemistry, seminoma, Sertoli cell tumor, tumor markers

Introduction

Testicular tumors arise from germ cells and sex-cord stromal elements of the testis [22], and are divided into four general categories: germ cell tumors including seminoma, teratoma, embryonal carcinoma, and yolk sac carcinoma arising from the germinal epithelium of the seminiferous tubules; sex-cord stromal tumors, including Sertoli cell tumor (SCT) and Leydig (interstitial) cell tumor; mixed germ cell sex-cord stromal tumors; and primary tumors not specific to the testes [22,30,32]. The major tumors are seminoma and SCT, which occur with equal frequency, showing a prevalence of 0.068-4.6% in mature and old male dogs [30,31,34]. Seminoma is derived from the germ cells that constitute the spermatogenic epithelium within the seminiferous tubules. SCT arises from the supporting cells within the seminiferous tubules. It is most common in dogs, but has also been reported in stallions, rams, bulls, goats, and cats [21,23].

In humans, testicular tumors are the most common cancers found in men between 15-35-years-of-age, where 90% are germ cell tumors [14,26,32]. Since the rate of testicular neoplasms is increasing, much research has been carried out to more accurately diagnose and manage these patients [2,11]. In particular, many immunohistochemical markers have been introduced to accurately establish histological diagnoses and to investigate tumor pathogenesis [3,18]. Markers including cytokeratins, c-KIT, CD30, epithelial membrane antigen, inhibin-alpha, OCT3/4, placental alkaline phosphatase (PLAP) and alpha fetoprotein (AFP) are sensitive and specific for the diagnosis of human testicular tumors [13,17,27,35]. Although tumor markers in canine testicular tumors have been studied, relatively less is known, which presently limits their use in diagnosis and evaluation of tumor pathogenesis.

In the present study, we examined tumor markers including PLAP, AFP, inhibin-alpha, vimentin, OCT3/4, CD30, desmin, and c-KIT to determine expression of these proteins and an appropriate antibody panel. To accomplish this, we employed immunohistochemical staining of canine seminomas and SCTs.
Materials and Methods

Tissues from testicular tumors in dogs

Testicular specimens from 35 male dogs with seminomas (n = 20) or SCTs (n = 15) were obtained from the files of the Department of Pathobiology, Small Animal Tumor Diagnostic Center, Konkuk University, Seoul, Korea. In addition, two normal testicular samples from neutered male dogs were used as negative controls. Histopathological analyses based on hematoxylin and eosin staining were performed.

Immunohistochemical staining

Each testis was fixed in 10% neutral buffered formalin. Blocks that contained testis tumor tissue were embedded in paraffin wax. Serial 4 μm-thick sections were acquired from each paraffin-block for immunohistochemical staining. Monoclonal and polyclonal antibodies (Table 1) included PLAP (Biogenex, USA), AFP (Biogenex), inhibin-alpha (Dako, USA), vimentin (Dako), OCT3/4 (Santa Cruz Biotechnology, USA), CD30 (Santa Cruz Biotechnology), desmin (Biogenex, USA), and c-KIT (Dako, USA). Sections were deparaffinized in xylene, rehydrated in a graded ethanol series, treated with 3% hydrogen peroxide solution for 20 min at room temperature, and washed three times with phosphate-buffered saline (PBS; pH 7.4, 137 mM NaCl, 2.7 mM KCl, 10 mM Na2HPO4, 2 mM KH2PO4). For inhibin-alpha, OCT3/4 and CD30, antigen retrieval was performed by heating slides in Tris-EDTA buffer (pH 9) in a microwave oven (650 W, high power) for 20 min. After 3 min washes with PBS, sections to be stained with AFP, vimentin, and c-KIT antibodies were incubated in a blocking solution of 5% normal goat serum (Vector Laboratories, USA) for 30 min. All primary antibodies were incubated with sections overnight at 4°C. To “visualize” immunolabeling, a two-step EnVision system (Dako, USA) was applied after removal of the primary antibody. In this system, EnVision rabbit/mouse reagent conjugated to horseradish peroxidase was applied for 40 min at room temperature. The slides were subsequently washed four times in PBS and incubated with the supplied substrates until the desired color intensity developed. The reaction was stopped by washing in distilled water. Sections were counterstained with Harris hematoxylin.

Digital image preparation and assessment of immunohistochemical labeling

Images were acquired using an Olympus BX41 microscope (Olympus, USA) fitted with a Leica DFC 290 digital camera (Leica, Switzerland) and analyzed for positive signals using Image-Pro Plus software ver. 4.1 (Media Cybernetics, USA). The immunolabeling was scored as positive if > 10% of tumor cells displayed staining.

Results

Characteristics of histopathology and immunostaining in seminoma and SCTs

The results of immunohistochemical studies are summarized in Tables 2 and 3. PLAP, AFP, inhibin-alpha, vimentin, desmin, and c-KIT were expressed in seminomas and SCTs, while OCT3/4 and CD30 were not expressed. In normal Leydig cells, inhibin alpha, vimentin, and desmin antibodies were weakly immunoreactive. Normal Sertoli cells had focal staining for vimentin and c-KIT. PLAP, AFP, OCT3/4, and CD30 produced no immunoreactivity in normal testis (data not shown).

Seminomas consisted of aggregates of germ cells that

Table 2. Frequency of expression of the antigen in canine seminomas (n = 20) and Sertoli cell tumors (n = 15)*

| Antibody | No. immunopositive cases (%) |
|----------|-----------------------------|
|          | Seminoma | Sertoli cell tumor |
| PLAP     | 4 (20%) | 6 (40%) |
| AFP      | 8 (40%) | 8 (53.3%) |
| Inhibin-α| 9 (45%) | 14 (93.3%) |
| Vimentin | 5 (25%) | 14 (93.3%) |
| OCT 3/4  | 0 (0%)  | 0 (0%) |
| c-KIT    | 20 (100%) | 10 (66.6%) |
| Desmin   | 6 (30%) | 5 (33.3%) |
| CD30     | 0 (0%)  | 0 (0%) |

*The result was scored as positive if > 10% of tumor cells showed the staining. PLAP: placental alkaline phosphatase, AFP: alpha fetoprotein.
Canine seminomas and Sertoli cell tumors

filled the lumens or sheets of the affected seminiferous tubules. These cells replaced the normal lining of spermatogenic and Sertoli cells. Large and irregular cellular aggregates and small clusters of cells were seen to varying extents. Dense fibrous bands subdivided the tumor into large discrete nodules. The tumor cells were large and polyhedral with vesicular nuclei and prominent nucleoli (Fig. 1A). PLAP staining was moderate-to-diffuse in four cases. AFP and inhibin-alpha were positive in eight and nine cases, respectively. AFP was diffusely expressed in tumor cells (Fig. 1B), while inhibin-alpha demonstrated diffuse immunoreactivity (Fig. 1C). Vimentin and desmin were positive in five and six separate cases, respectively. Expression of vimentin produced strongly positive immunoreactivity in some tumor cells within some seminomas (Fig. 1D). Expression of desmin was diffuse and focal to the cytoplasm of tumor cells (Fig. 1E). No OCT3/4 or CD30 staining was evident in the tumors (data not shown). C-KIT was strongly positive in all cases (Fig. 1F).

In SCTs, there was abundant fibrous tissue stroma. Cells within the tumor resembled Sertoli cells that normally populate the seminiferous tubules, and were arranged into sheets or tubules separated by fibrous connective tissue. The tumor cells had small, round or elongated nuclei with an eosinophilic cytoplasm (Fig. 2A). Of 15 SCT samples, six cases were positive for PLAP with weak and focal immunostaining. In eight cases, AFP was expressed in the cytoplasm of tumor cells (Fig. 2B). Fourteen cases were positive for inhibin-alpha and vimentin. While the tumor cells were strongly positive for inhibin-alpha (Fig. 2C), they were only weakly positive for vimentin (Fig. 2D). All SCTs were negative for OCT3/4 (data not shown). CD30 was not expressed in tumor cells (data not shown). Focal immunostaining of desmin was observed in five cases (Fig. 2E). Ten cases were positive for c-KIT, where its expression was distributed diffusely but strongly in the cytoplasm of tumor cells (Fig. 2F).

Discussion

Primary testicular tumors are common in mature and old male dogs [34]. The main types of testicular tumors in dogs are seminomas and SCTs, which are associated with

Cryptorchidism. In humans, testicular tumors are the most common cancers found in men, with an increasing rate of incidence [26,32]. Substantial research on human testicular tumors has resulted in more accurate diagnoses and better management of patients [3,11]. In particular, many tumor markers have been found for tumor pathogenesis [1,4,6]. Of these markers, cytokeratins, c-KIT, CD30, epithelial membrane antigen, inhibin-alpha, OCT3/4, PLAP, and AFP are widely used because of their sensitivity and specificity. The usefulness of these as tumor markers has been assessed in many studies [13,17,27,35]. Canine testicular tumor markers have been studied [23,28,34]. However, such veterinary tumor markers in male canine patients still require more study to be useful in accurate diagnosis. Thus, the purpose of our present study was to establish the specificity of tumor markers including PLAP, AFP, inhibin-alpha, vimentin, OCT3/4, CD30, desmin, and c-KIT in canine seminoma and SCT.

In the current seminoma series, c-KIT was found to be the most sensitive marker, because tumor cells of all seminoma cases were homogeneously and strongly positive for the antibody. c-KIT is a product of the c-KIT oncogene, which encodes a type III transmembrane tyrosine kinase receptor that is required in normal spermatogenesis. High expression of c-KIT is found in human testicular germ cell tumors, especially in human seminoma [26]. KIT signal transduction appears to be an important pathway for carcinogenesis of seminoma [12]. Our result demonstrates that c-KIT is potently expressed and is potentially a specific tumor marker in canine seminoma, similar to human tumors. OCT3/4, also known as otf3 or pou5f1, is a member of the POU family of transcription factors expressed in pluripotent mouse and human embryonic stem and germ cells [7,10,29]. Unexpectedly, OCT3/4, which is regarded as a highly sensitive marker for human seminoma and embryonal carcinoma [2,33], was not expressed in any canine seminoma. OCT3/4 may not be a reliably specific tumor marker in canine seminoma. PLAP, a membrane-bound enzyme normally synthesized by placental syncytiotrophoblasts [4], has been widely applied in the significant markers of human seminoma. In contrast, PLAP staining was detected weakly and heterogeneously in canine SCTs. Although a positive reaction was observed in 20% of cases, the result was less significant than that observed in human seminoma PLAP immunostaining. This result might be related with the classification of testicular tumors including two types of seminoma. The first type is classical seminoma (SE) and the second type is spermatocytic seminoma (SS). Grieco et al. [8] showed that neoplastic cells are immunoreactive for PLAP in all cases with SE. Neoplastic cells in SS are essentially negative for PLAP [8]. Therefore, our result combined with the observations of Grieco et al. [8] indicate that 20% cases displaying a positive reaction were likely SE and the 80% cases displaying negative reaction were SS. Inhibin-alpha, a subunit of inhibin, is secreted mainly from testicular Sertoli cells with an additional small contribution from Leydig cells [4,34]. Although little is known about the cells secreting inhibin in primary testicular tumors of humans and older animals [5,9,16], inhibin immunoreactivity has been biochemically estimated in human and canine
testicular tumors. In the current seminoma series, inhibin-alpha was observed in the cytoplasm of tumors cell in 45% of the cases. Vimentin and desmin was expressed in 25% and 30%, respectively, of canine seminoma samples. As for vimentin and desmin, unlike the diffuse cytoplasmic staining present in SCTs, immunoreactivity in seminomas was observed confined to the cytoplasm of the tumor cells. Vimentin and desmin are known as markers of mesenchymal origin tumors including connective tissue, endothelium, hematopoietic cell, and muscle. Because of the origin of seminoma is germ cells originating from epithelial tissue, vimentin and desmin are not appropriate markers. CD30 is a membrane glycoprotein of the tumor necrosis factor receptor superfamily, which plays a useful role in identifying primary embryonal carcinoma in humans [33]. CD30 is also useful for distinguishing embryonal carcinoma from seminoma [19]. When the fixation is not adequate, seminoma may be confused with the solid pattern of embryonal carcinoma [36]. The distinction between seminoma and embryonal carcinoma is very important because the treatment differs. Our result shows that CD30 was not expressed in canine seminoma. Although there was no case of embryonal carcinoma in this study, this result suggests that CD30 can be used to differentiate embryonal carcinoma from seminoma.

These immunohistochemical results demonstrate that c-KIT is a sensitive marker for seminoma in dogs. In human seminoma, c-KIT is expressed in seminomas at the high prevalence rate of 88-100%, making it one of the most effective immunohistochemical markers [1,18,26]. Although PLAP, AFP, inhibin-alpha, desmin, and vimentin immunoreactivity were observed in this study, they did not demonstrate significant results. The immunoreactivity of SCTs indicates that inhibin-alpha and vimentin were the most remarkable immunoreactivity of all the antibodies used in this study. Inhibin-alpha and vimentin were expressed with a high prevalence rate of 93.3% and were diffusely and moderately evident in the cytoplasm of neoplastic cells. Previous studies did not detect immunohistochemical expression of inhibin-alpha in SCTs in dogs [31,34]. Although PLAP, AFP, inhibin-alpha, desmin, and vimentin immunoreactivity were observed in this study, they did not demonstrate significant results.

In conclusion, the results of this study demonstrate that c-KIT is the most sensitive marker in canine seminomas, while inhibin-alpha and vimentin are the most sensitive markers in canine SCTs. Although OCT3/4 and PLAP are regarded as the most suitable immunohistochemical markers in human germ cell tumors including seminoma, these were either not expressed or only weakly expressed in the canine seminomas presently examined. One interpretation of these results might be that all the antibodies used in this experiment were produced against human proteins. As a result, these antibodies might fail to detect canine PLAP or OCT3/4. However, it is also reasonable to think that OCT3/4 and PLAP are not effective markers for canine seminoma. Inhibin-alpha and vimentin were expressed markedly in canine SCTs in a similar fashion as in human cells. Therefore, these proteins are specific markers in canine SCTs.
