Stomach cancer incidence in a cohort of fishermen in Singapore

by Jeyarajah Jeyaratnam, MFOM,1 James Lee, PhD,1 Hin Peng Lee, MFCM,1 Wai On Phoon, FFOM2

JEYARATNAM J, LEE J, LEE HP, PHOON WO. Stomach cancer incidence in a cohort of fishermen in Singapore. Scand J Work Environ Health 13 (1987) 524—526. A retrospective cohort study of 279 Chinese fishermen in Singapore was undertaken to examine the possibility of an elevated incidence of stomach cancer. The fishermen as a group had a greater than twofold excess in stomach cancer relative to Chinese men of similar age and over the same calendar years in Singapore, but the difference was not statistically significant. On further examination it was revealed that the four stomach cancer cases were observed among the subgroup of divers. The standardized incidence ratio for the divers was 4.3, which was significantly greater than unity. There was no evidence of an increased risk for cancer of any other site (lung, nasopharynx and liver) in this cohort. Dietary factors are suggested as a possible explanation for the observation of an increased risk for stomach cancer among fishermen, but larger studies are required to test this hypothesis.

Key terms: epidemiology, modified life table, occupational cancer, standardized incidence ratio.

In Singapore stomach cancer ranks second on the list of cancers for men and fourth for women (20). In addition there is a high incidence of stomach cancer in Japan and other parts of Asia and South America, but in North America and Europe the incidence is low and is decreasing (22, 23). Studies indicate a reasonably consistent association between stomach cancer and various aspects of environment and life-style, particularly dietary intake. For instance, it has been documented that a decline in the incidence of stomach cancer has occurred over several generations among Japanese migrants to the United States, the indication being that environmental or life-style related factors are involved (12). Dietary factors such as salt intake in food (10), salted or preserved foods, and smoked foods (3, 7, 9, 11, 24) and other personal habits (8) have been shown to be correlated with stomach cancer.

A relationship between occupation and stomach cancer is not well established. A slight excess risk for selected occupational groups such as miners (5, 14), asbestos workers (6, 19), rubber workers (15), and metal product workers (13, 17) has been noted, however. These studies have suggested a possible link between stomach cancer and various factors in the work environment. None of these studies incriminated a possible dietary factor as being responsible for the observed association. The present study was initiated to examine the incidence of stomach cancer among diver fishermen in Singapore because of a clinical impression of one of the authors (JJ) of an elevated incidence of stomach cancer among this group of workers.

Materials and methods

The study cohort comprised 320 Chinese registered as members of an association of fishermen in Singapore. These men fish (17) in the South China Sea and the Indian Ocean about 300 to 1 500 km from Singapore. The subjects were registered as fishermen with the association during the period between 1947 and 1980, and the cohort was monitored until August 1985. The fishermen so identified were traced, and information was obtained on their age, date of commencement of work, duration of employment if no longer working as a fisherman, nature of work (diver or nondiver), and illnesses. Incidence data were obtained from the association register, medical records, and interviews of family members during the survey. The diagnoses for cancer were verified from the database of the Singapore Cancer Registry. Information was available on 279 (180 divers and 99 nondivers) of the 320 fishermen, the response rate being 87 %. The total person-years of follow-up was 3 548 for the divers (average of 19.7 years per diver) and 2 050 for the nondivers (average of 20.7 years per nondiver).

A modified life-table method (16) was employed in which person-years of observation were cumulated for each exposure duration in five-year age groups and five-year calendar intervals. These data were then used to generate expected numbers of site-specific cancer incidence cases based on the age and calendar-specific incidence rates of Chinese men in Singapore. The standardized incidence ratio (SIR) was computed as the ratio of the observed number of cases to the expected number of cases of site-specific cancer. Statistical significance for the SIR was determined under the assumption of a Poisson distribution for the observed

number of cancer cases, as described by Bailar & Ederer (1). All the statistical computations were performed with the man-years FORTRAN program (4).

Results

Table 1 shows the observed and expected numbers of stomach cancer among the fishermen and their corresponding SIR values. The SIR for all the subjects was 2.3. Thus the fishermen as a group had a greater than twofold increase in risk for stomach cancer relative to Chinese men of similar age and over the same calendar years in Singapore, but the SIR was not close to statistical significance (95% confidence interval 0.6—5.8). However, it is noteworthy that all four stomach cancer cases occurred among the divers, for an SIR of 4.3, which was significantly greater than unity (95% confidence interval 1.2—11.0).

All four stomach cancer cases occurred in men between the ages of 35 and 59 years. One case was identified within five years of the man becoming a fisherman, one between five and ten years, and two after more than ten years. As of August 1985, the mean age of the divers was 48.1 (SD 10.6) years, and that of the nondivers was 51.3 (SD 12.8) years.

In addition to the four stomach cancer cases, there were two cases of lung cancer, one of nasopharyngeal cancer, and one of liver cancer among the fishermen. The SIR of each cancer site for all the subjects was lower than unity, although the difference was not statistically significant. It was again noted that these cancers occurred only in the divers, but none of their SIR values was significantly in excess of unity.

Discussion

This study showed that Chinese fishermen in Singapore have a greater than twofold likelihood of developing stomach cancer in comparison to the corresponding general population. When this group was divided into divers and nondivers, it was observed that all of the stomach cancer cases occurred only among the divers, with a greater than fourfold risk relative to the general population (table 1). It is noteworthy that there was no evidence of an increased risk for cancer of other sites among this group of fishermen in comparison to the general population.

A possible explanation for the observation of a higher incidence of stomach cancer in this group could be associated with the known practice of these fishermen having an increased intake of salted fish or “rotted” fish or both in their diet. The process of salting fish increases the content of nitrates in the diet. Furthermore, this particular type of “rotted” fish could result in bacterial contamination of the stomach. The nitrates are subsequently reduced to nitrites and the bacterial flora could lead to the conversion of the nitrites to carcinogenic N-nitroso compounds. A similar mechanism has been postulated for stomach cancer associated with iron deficiency and pernicious anemia (2, 18). In addition to this possible carcinogenic mechanism, the situation is further aggravated by the fact that the fishermen’s diet lacks fresh vegetables, a source of vitamin A (21, 25). It has been recognized that the presence of vitamin A in the diet may have a protective effect on the gastric mucosa and thereby may prevent the occurrence of stomach cancer.

The present study points toward an elevated incidence of stomach cancer for Chinese fishermen in Singapore, particularly among divers. The possibility of an associated dietary factor is considered a plausible explanation for the observation. We plan to investigate this possibility in the future by undertaking a comparative study of the dietary habits and life-style of fishermen and nonfishermen.

Recommendations

It is noteworthy that all four stomach cancer cases occurred in men between the ages of 35 and 59 years. One case was identified within five years of the man becoming a fisherman, one between five and ten years, and two after more than ten years. As of August 1985, the mean age of the divers was 48.1 (SD 10.6) years, and that of the nondivers was 51.3 (SD 12.8) years.

In addition to the four stomach cancer cases, there were two cases of lung cancer, one of nasopharyngeal cancer, and one of liver cancer among the fishermen. The SIR of each cancer site for all the subjects was lower than unity, although the difference was not statistically significant. It was again noted that these cancers occurred only in the divers, but none of their SIR values was significantly in excess of unity.

Discussion

This study showed that Chinese fishermen in Singapore have a greater than twofold likelihood of developing stomach cancer in comparison to the corresponding general population. When this group was divided into divers and nondivers, it was observed that all of the stomach cancer cases occurred only among the divers, with a greater than fourfold risk relative to the general population (table 1). It is noteworthy that there was no evidence of an increased risk for cancer of other sites among this group of fishermen in comparison to the general population.

A possible explanation for the observation of a higher incidence of stomach cancer in this group could be associated with the known practice of these fishermen having an increased intake of salted fish or “rotted” fish or both in their diet. The process of salting fish increases the content of nitrates in the diet. Furthermore, this particular type of “rotted” fish could result in bacterial contamination of the stomach. The nitrates are subsequently reduced to nitrites and the bacterial flora could lead to the conversion of the nitrites to carcinogenic N-nitroso compounds. A similar mechanism has been postulated for stomach cancer associated with iron deficiency and pernicious anemia (2, 18). In addition to this possible carcinogenic mechanism, the situation is further aggravated by the fact that the fishermen’s diet lacks fresh vegetables, a source of vitamin A (21, 25). It has been recognized that the presence of vitamin A in the diet may have a protective effect on the gastric mucosa and thereby may prevent the occurrence of stomach cancer.

The present study points toward an elevated incidence of stomach cancer for Chinese fishermen in Singapore, particularly among divers. The possibility of an associated dietary factor is considered a plausible explanation for the observation. We plan to investigate this possibility in the future by undertaking a comparative study of the dietary habits and life-style of fishermen and nonfishermen.

Table 1. Stomach cancer incidence among Chinese fishermen grouped as divers and nondivers. (O = observed cases, E = expected cases, SIR = standardized incidence ratio, 95% CI = confidence interval)

| Fishermen  | Person-years at risk | O | E | SIR | 95% CI |
|------------|----------------------|---|---|-----|-------|
| Divers (N = 180) | 3,448 | 4 | 0.93 | 4.29 | 1.2—11.0 |
| Nondivers (N = 99) | 2,050 | 0 | 0.84 | — | — |
| Total (N = 279) | 5,598 | 4 | 1.77 | 2.25 | 0.6—5.8 |
