Face Dimensions of General-Purpose Cutting Planes for Mixed-Integer Linear Programs

Matthias Walter∗

November 11, 2020

Abstract

Cutting planes are a key ingredient to successfully solve mixed-integer linear programs. For specific problems, their strength is often theoretically assessed by showing that they are facet-defining for the corresponding mixed-integer hull. In this paper we experimentally investigate the dimensions of faces induced by general-purpose cutting planes generated by a state-of-the-art solver. Therefore, we relate the dimension of each cutting plane to its impact in a branch-and-bound algorithm.

1 Introduction

We consider the mixed-integer program

\begin{align}
\max c^\top x \quad & \tag{1a} \\
\text{s.t.} \quad Ax & \leq b \quad \tag{1b} \\
x_i \in \mathbb{Z} \quad & \forall i \in I \quad \tag{1c}
\end{align}

for a matrix $A \in \mathbb{R}^{m \times n}$, vectors $c \in \mathbb{R}^n$ and $b \in \mathbb{R}^m$ and a subset $I \subseteq \{1, 2, \ldots, n\}$ of integer variables. Let $P := \text{conv}\{x \in \mathbb{R}^n : x \text{ satisfies (1b) and (1c)}\}$ denote the corresponding mixed-integer hull. A cutting plane for (1) is an inequality $a^\top x \leq \beta$ that is valid for $P$ (and possibly invalid for some point computed during branch-and-cut). Such a valid inequality induces the face $F := \{x \in P : a^\top x = \beta\}$ of $P$. For more background on polyhedra we refer to [10].

To tackle specific problems, one often tries to find facet-defining inequalities, which are inequalities whose induced face $F$ satisfies $\dim(F) = \dim(P) - 1$. This is justified by the fact that any system $Cx \leq d$ with $P = \{x : Cx \leq d\}$ has to contain an inequality that induces $F$. Since the dimension of a face can vary between $-1$ (no $x \in P$ satisfies $a^\top x = \beta$) and $\dim(P)$ (all $x \in P$ satisfy $a^\top x = \beta$), the following hypothesis is a reasonable generalization of facetness as a strength indicator.

Hypothesis 1. The practical strength of an inequality correlates with the dimension of its induced face.

There is no unified notion of the practical strength of an inequality, but we will later define one that is related to its impact in a branch-and-bound algorithm. The main goal of this paper is to computationally test this hypothesis for general-purpose cutting planes used in MIP solvers.

Outline. In Section 2 we present the algorithm we used to compute dimensions. Section 3 is dedicated to the score we used to assess a cutting plane’s impact, and in Section 4 we present our findings, in particular regarding Hypothesis 1.

2 Computing the dimension of a face

This section is concerned about how to effectively compute the dimension of \( P \) or of one of its faces \( P \) induced by some valid inequality \( a^T x \leq \beta \). In our experiments we will consider instances with several hundreds variables, and hence the enumeration of all vertices of \( P \) or \( F \) is typically impossible. Instead, we use an oracle-based approach. An optimization oracle for \( P \) is a black-box subroutine that can solve any linear program over the polyhedron \( P \), i.e., for any given \( w \in \mathbb{R}^n \) it can solve

\[
\text{max } w^T x \text{ s.t. } x \in P.
\]

(2)

In case (2) is feasible and bounded, the oracle shall return an optimal solution, and in case it is feasible and unbounded, it shall return an unbounded direction. Note that for such an oracle we neither require all vertices of \( P \) nor all valid (irredundant) inequalities. Indeed, we can use any MIP solver and apply it to problem (1) with \( c := w \).

We now discuss how one can compute \( \dim(P) \) by only accessing an optimization oracle. To keep the presentation simple we assume that \( P \) is bounded, although our implementation can handle unbounded polyhedra as well. The algorithm maintains a set \( X \subseteq P \) of affinely independent points and a system \( Dx = e \) of valid equations, where \( D \) has full row-rank \( r \). Hence, \( \dim(X) \leq \dim(P) \leq n - r \) holds throughout and the algorithm works by either increasing \( \dim(X) \) or \( r \) in every iteration. The details are provided in Algorithm 1.

**Algorithm 1: Affine hull of a polytope via optimization oracle**

**Input:** Optimization oracle for a polytope \( \emptyset \neq P \subseteq \mathbb{R}^n \).

**Output:** Affine basis \( X \) of \( \text{aff}(P) \), non-redundant system \( Dx = e \) with \( \text{aff}(P) = \{ x \in \mathbb{R}^n : Dx = e \} \).

1. Initialize \( X := \emptyset \) and \( Dx = e \) empty.
2. while \( |X| + 1 < n - |\text{rows}(D)| \) do
3.   Compute a direction vector \( d := \text{aff}(X)^\perp \setminus \text{span(rows}(D)) \).
4.   Query the oracle to maximize \( d^T x \) over \( x \in P \) and let \( x^+ := \text{arg max}\{d^T x : x \in P\} \).
5.   Query the oracle to maximize \( -d^T x \) over \( x \in P \) and let \( x^- := \text{arg min}\{d^T x : x \in P\} \).
6.   if \( d^T x^+ = d^T x^- \) then
7.     Add equation \( d^T x = d^T x^+ \) to system \( Dx = e \).
8.   else if \( X = \emptyset \) then set \( X := \{x^+, x^-\} \).
9.   else
10.      Let \( \gamma := d^T x \) for some \( x \in X \).
11.     if \( d^T x^+ \neq \gamma \) then set \( X := X \cup \{x^+\} \).
12.    else set \( X := X \cup \{x^-\} \).
13.   end
14. end
15. return \( (X, Dx = e) \).

**Proposition 2.** For an optimization oracle for a non-empty polytope \( P \subseteq \mathbb{R}^n \), Algorithm 1 requires \( 2n \) oracle queries to compute a set \( X \subseteq P \) with \( |X| = \dim(P) + 1 \) and a system \( Dx = e \) of \( n - \dim(P) \) equations satisfying \( \text{aff}(P) = \text{aff}(X) = \{ x \in \mathbb{R}^n : Dx = e \} \).

**Proof.** Since every point \( x \in X \) was computed by the optimization oracle, we have \( X \subseteq P \). Moreover, \( Dx = e \) is valid for \( P \) since for each equation \( d^T x = \gamma \), \( \min\{d^T x : x \in P\} = \gamma = \max\{d^T x : x \in P\} \) holds. We now prove by induction on the number of iterations that in every iteration of the algorithm, the points \( x \in X \) are affinely independent and that the rows of \( D \) are linearly independent.

Initially, this is invariant holds because \( X = \emptyset \) and \( D \) has no rows. Whenever an equation \( d^T x = d^T x^+ \) is added to \( Dx = e \) in step 7, the vector \( d \) is linearly independent to the rows of \( D \) (see step 3). If in step 8, \( X \) is initialized with a single point, it is clearly affinely independent.
Similarly, the two points in step 10 also form an affinely independent set since \( a^\top x^+ > d^\top x^- \) implies \( x^+ \neq x^- \). Suppose \( X \) is augmented by \( \bar{x} \) in step 13 or by \( \tilde{x} \) in step 14. Note that by the choice of \( d \) in step 3, \( d^\top x = \gamma \) holds for all \( x \in X \). Due to \( d^\top \bar{x} \neq \gamma \), \( U \cup \{ \bar{x} \} \) remains affinely independent.

After the first iteration, we have \(|X| + |\text{rows}(C)| = 2\); and in every further iteration, this quantity increases by 1. Hence, the algorithm requires \( n \) iterations, each of which performs 2 oracle queries. The result follows.

For a proof that the number \( 2n \) of oracle queries is optimal we refer to [11].

**Implementation details.** We now describe some details of the implementation within the software framework Ipopt [12]. In the description of Algorithm 1 we did not specify step 3 precisely. While one may enforce the requirement \( d \notin \text{span(rows}(D)) \) via \( d \in \text{rows}(D) \), it turned out that this is numerically less stable than first computing a basis of \( \text{aff}(X)^{+} \) and selecting a basis element \( d \) that is not in the span of \( D \)'s rows. Moreover, we can take \( d \)'s sparsity and other numerical properties into account. Sparsity can speed-up the overall computation since very sparse objective vectors are sometimes easier to optimize for a MIP solver. In theory, for all \( x \in X \), the products \( d^\top x \) have the same value. However, due to floating-point arithmetic the computed values may differ. It turned out that preferring directions \( d \) for which the range of these products is small helps to avoid numerical difficulties.

In our application we compute the dimension of \( P \) and of several of its faces. We can exploit this by caching all points \( x \in P \) returned by an optimization oracle in a set \( \hat{X} \). Then, for each face \( F \) induced by an inequality \( a^\top x \leq \beta \) we can then compute the set \( X_F \) by \( \{ x \in X : a^\top x = \beta \} \). Before querying the oracle we can then check the set \( X_F \) for a point with sufficiently large objective value, which saves two calls to the MIP solvers.

Let \( \bar{D}x = e \) be the equation system returned by Algorithm 1 for \( P \). Now, for a face \( F \) induced by inequality \( a^\top x \leq \beta \) we can initialize \( \bar{D}x = e \) in the algorithm by \( Dx = \bar{e} \). Moreover, if \( a^\top x = \beta \) is not implied by \( Dx = \bar{e} \) we add this equation to \( Dx = \bar{e} \) as well.

Since the algorithm is implemented in floating-point arithmetic, errors can occur which may lead to wrong dimension results. We checked the results using an exact arithmetic implementation of Algorithm 1 for easier instances (with less than 200 variables). For these, the computed dimension varied by at most 2 from the true dimension.

In a first implementation, our code frequently reported dimension \(-1\), and it turned out that often the right-hand side was only slightly larger than needed to make the inequality supporting. Thus, for each inequality \( a^\top x \leq \beta \), normalized to \( ||a||_2 = 1 \), we computed \( \beta^{\text{true}} := \max\{a^\top x : x \in P\} \) by a single oracle query. Whenever we observed \( \beta < \beta^{\text{true}} - 10^{-4} \), we considered the cut \( a^\top x \leq \beta \) as invalid (indicated by the symbol \( \dagger \)). If \( \beta > \beta^{\text{true}} + 10^{-4} \), we declare the cut to be non-supporting. Otherwise, we replace \( \beta \) by \( \beta^{\text{true}} \) before running Algorithm 1.

### 3 Measuring the strength of a single inequality

In this section we introduce our **cut impact measure** for indicating, for a given cutting plane \( a^\top x \leq \beta \), how useful its addition in the context of branch-and-cut is. The main goal of solving an LP at a branch-and-bound node is to determine a dual bound of the current subproblem. If this bound is at most the value of the best feasible solution known so far, then the subproblem can be discarded. Thus, we consider the value of such a bound (after adding a certain cut) in relation to the problem’s optimum \( z^* := \max\{c^\top x : Ax \leq b, \; x \in \mathbb{Z} \; \forall i \in I\} \) and the value \( z^{\text{LP}} := \max\{c^\top x : Ax \leq b\} \) of the LP relaxation.

Our first approach was to just evaluate the dual bound obtained from the LP relaxation \( Ax \leq b \) augmented by \( a^\top x \leq \beta \). However, adding a single inequality often does not cut off the optimal face of the LP relaxation, which means that the bound does not change. In a second attempt we tried to evaluate the dual bound of the LP relaxation augmented by a random selection of \( k \) cutting planes. However, the variance of the resulting cut impact measure was very large even after averaging over 10,000 such selections.
As a consequence, we discarded cut impact measures based on the combined impact of several cutting planes. Instead we carried out the following steps for given cutting planes $a_i^T x \leq \beta_i$:

1. Compute the optimum $z^*$ and optimum solution $x^* \in P$.
2. Compute $z^{LP}$.
3. For $i = 0, 1, 2, \ldots, k$, solve
   \[
   \max c^T x \text{ s.t. } Ax \leq b, \ x_j \in \mathbb{Z} \ \forall j \in I \text{ and } a_i^T x \leq \beta_i \text{ if } i \geq 1
   \]
   with $x^*$ as an initial incumbent, with presolve, cutting planes and heuristics disabled and where a time limit of 60 seconds is enforced.
4. Let $N$ denote the minimum number of branch-and-bound nodes used in any these $k + 1$ runs.
5. For $i = 0, 1, \ldots, k$, let $z^i$ be the dual bound obtained in run $i$ when stopping after $N$ branch-and-bound nodes. For $i \geq 1$, the closed gap of cut $i$ is defined as $(z^i - z^{LP})/(z^* - z^{LP})$. For $i = 0$, this yields the closed gap without cuts.

Remarks. The closed gap is essentially the dual bound, normalized such that a value of 0 means no bound improvement over the root LP bound without cuts and a value of 1 means that the instance was solved to optimality. The effective limit of $N$ branch-and-bound nodes was introduced such that all runs reach this limit. This circumvents the question of how to compare runs in which the problem was solved to optimality with those that could not solve it. For all runs, presolve and domain propagation were disabled due to our focus on the branch-and-bound algorithm itself. To avoid interaction with heuristics, the latter were disabled, but the optimal solution $x^*$ was provided.

4 Computational study

In order to test Hypothesis 1 we considered the 65 instances from the MIPLIB 3 [9]. For each of them we computed the dimension of the mixed-integer hull $P$, imposing a time limit of 10 minutes. Moreover, we ran the state-of-the-art solver SCIP [3] and collected all cutting planes generated in the root node, including those that were discarded by SCIP’s cut selection routine. For each of the cuts we computed the dimension of its induced face (see Section 2) as well as the closed gap after processing $N$ (as defined in Section 3) branch-and-bound nodes.

While for instances.air03, air05, nw04, no cuts were generated by SCIP, our implementation of Algorithm 1 ran into numerical difficulties during the computation of $\text{dim}(P)$ for setich. Moreover, $\text{dim}(P)$ could not be computed within 10 minutes for instances air04, arki001, cap6000, dano3mip, danoint, dsbmip, fast0507, gesa2_0, gesa3_0, l152lav, mas74, misc06, mitre, mkc, mod010, mod011, pk1, pp08aCUTS, pp08a, qnet1, rentacar, rout and swath.

We evaluated the remaining 37 instances, whose characteristic data is shown in Table 1. We distinguish how many cuts SCIP found by which cut separation method, in particular to investigate whether certain separation routines tend to generate cuts with low- or high-dimensional faces.

We verified some of the invalid cutting planes manually, i.e., checked that these cuts are generated by SCIP and that there exists a feasible solution that is indeed cut off. The most likely reason for their occurrence is that SCIP performed dual reductions although we disabled them via corresponding parameters.

---

1 All experiments were carried out on a single core of an Intel Core i3 CPU running at 2.10 GHz with 8 GB RAM.
2 We disabled presolve, domain propagation, dual reductions, symmetry, and restarts.
3 We set misc/allowweakdualreds and misc/allowstrongdualreds to false.
Table 1: Characteristics of the relevant 37 instances with number of successfully analyzed cuts, failures (numerical problems 0/0, timeouts ⚤, invalid cuts ⚽), dimension of the mixed-integer hull, and number $N$ of branch-and-bound nodes (see Section 3).

Since the results on face dimensions and cut strength turned out to be very instance-specific, we created one plot per instance. We omit the ones for p2756 (too many failures, see Table 1), blend2 (only 7 cuts analyzed), enigma (dim(P) = 3 is very small), and for markshare1, markshare2 and noswot (all cuts were ineffective). Moreover, we present several plots in the Appendix A since these are similar to those of other instances.

The plots show the dimension of the cuts (horizontal axis, rounded to 19 groups) together with their closed gap (vertical axis, 14 groups) according to Section 3. Each circle corresponds to a nonempty set of cuts, where the segments depict the respective cut classes (see Table 1) and their color depicts the number \( k \) of cuts, where the largest occurring number \( L \) is specified in the caption. The colors are red (0.9\( L < k \leq L \)), orange (0.7\( L < k \leq 0.9L \)), yellow (0.5\( L < k \leq 0.7L \)), green (0.3\( L < k \leq 0.5L \)), turquoise (0.1\( L < k \leq 0.3L \)) and blue (1 \( \leq k \leq 0.1L \)). For instance, the circle for fixnet6 containing a red and a turquoise segment subsumes cutting planes with face dimensions between 730 and 777, and closed gap of approximately 0.45. As the legend next to the plot indicates, this circle represents \( k \in [109, 121] \) c-MIR cuts and \( k' \in [13, 36] \) multi-commodity flow cuts. The dashed horizontal line indicates the closed gap without cuts (see Section 3).

The first three plots already highlight that the results are very heterogeneous: while the faces of the strongest cuts in fixnet6 have a high dimension, the strongest ones for misc03 are not even supporting. Even when considering non-supporting cuts as outliers, the dimension does not indicate practical strength, as the plot for gt2 shows. A quick look at the other plots lets us conclude that Hypothesis 1 is false — at least for the strength measure from Section 3.
The dashed line for \texttt{harp2} shows that adding a single cut does not necessarily help in branch-and-bound, which may be due to side-effects such as different branching decisions. For some instances, such as \texttt{mod008}, the cuts’ face dimensions are well distributed. In contrast to this, some instances exhibit only very few distinct dimension values, e.g., only non-supporting cuts for \texttt{qiu}. Interestingly, the 6246 cuts for \texttt{seymour} induce only empty faces as well as faces with dimensions between 1218 and 1254. This can partially be explained via the cut classes. On the one hand, all generated strengthened Chvátal-Gomory cuts are non-supporting. On the other hand, some of the c-MIR cuts and \{0,1/2\}-cuts are non-supporting while others induce faces of very high dimension.

In general we don’t see an indication that cuts from certain classes induce higher dimensional faces than others. At first glance, such a pattern is apparent for \texttt{misc07} (at dimensions 130–160), however one has to keep in mind that these blue segments constitute a minority of the cuts. In line with that, the majority of the cuts for \texttt{fiber} is concentrated around dimension 900 with a closed gap similar to that without cuts.
Despite the heterogeneity of the results, one observation is common to many instances: the distribution of the face dimensions is biased towards $-1$ and high-dimensions, i.e., not many cuts inducing low dimensional faces are generated.

A corresponding histogram is depicted in Fig. 1. We conjecture that the high dimensions occur because lifting and strengthening techniques for cutting planes are quite evolved.

![Figure 1: Distribution of relative dimensions over the 37 instances from Table 1 except for p2756 (avoiding a bias due to many failures dimension computations). A cut of dimension $k$ in an instance having $\ell$ cuts and with $\text{dim}(P) = d$ contributes $1/(36\ell)$ to its bar. For $k = -1$ (resp. $k = d$), this is $\emptyset$ (resp. $\infty$), and it is $k/(d-1)$ otherwise.](image)

The first bar in Fig. 1 indicates that for an instance chosen uniformly at random among the ones we considered and then a randomly chosen cut for this instance, this cut is non-supporting with probability greater than 35%. This is remarkably high and thus we conclude this paper by proposing to investigate means to (heuristically) test for such a situation, with the goal of strengthening a non-supporting cutting plane by a reduction its right-hand side.

**Acknowledgments.** We thank R. Hoeksma and M. Uetz as well as the SCIP development team, in particular A. Gleixner, C. Hojny and M. Pfetsch for valuable suggestions on the computational experiments and their presentation.

A  Additional plots

Here we provide additional instance-specific plots. This underlines the conclusions drawn in Section 4 and allows inspection of results for instances with certain characteristics (see Table 1).

1. bell3a: $L = 5$ cuts
2. bell5: $L = 3$ cuts
3. dcmulti: $L = 38$ cuts
4. egout: $L = 31$ cuts
5. flugpl: $L = 11$ cuts
6. gen: $L = 5$ cuts
