Abstract. The imprint of neutrino oscillations on the Cosmic Microwave Background (CMB) anisotropy and polarization power spectra is evaluated in a $\Lambda$CDM model with two active neutrino flavors, consistent with the structure formation models and the atmospheric neutrino oscillations data. By using the Fisher information matrix method we find that the neutrino oscillations could be detected by Planck surveyor if the present value of the lepton asymmetry $L_\nu \geq 4.5 \times 10^{-3}$, the difference of the neutrino squared masses $\Delta m^2 \geq 9.7 \times 10^{-3}$eV$^2$ and the vacuum mixing angle $\sin^2 2\theta_0 \geq 0.13$, showing the existence of a significant overlap between the region of the oscillation parameter space that can be measured by Planck surveyor and that implied by the atmospheric neutrino oscillations data.

Key words: Cosmology: cosmic microwave background – dark matter – large scale structure – Elementary particles

1. Introduction

The atmospheric neutrino results from Super-Kamiokande (Fukuda et al. 1998) and MACRO (Ambrosio et al. 1998) experiments indicate that neutrinos oscillate. Those data are consistent with $\nu_\mu \leftrightarrow \nu_\tau$ oscillations, but do not exclude $\nu_\mu$ oscillations to a sterile neutrino $\nu_s$ (see e.g. Foot et al. 1996; Foot & Volkas 1997, 1999). The small value of the difference of the squared masses ($5 \times 10^{-4}$eV$^2 \leq \Delta m^2 \leq 6 \times 10^{-3}$eV$^2$) and the strong mixing angle ($\sin^2 2\theta_0 \geq 0.82$) suggest that these neutrinos are nearly equal in mass as predicted by many models of particle physics beyond the standard model (see e.g. Primack & Gross 1998 and the references therein). Also, the LSND experiment (Athanassopoulos et al. 1998) support $\nu_\mu \leftrightarrow \nu_e$ oscillations with $\Delta m^2 \leq 0.2$eV$^2$ and other different types of solar neutrino experiments (Bahcall et al. 1998) suggest that $\nu_e$ could oscillate to a sterile neutrino $\nu_e \leftrightarrow \nu_s$ with $\Delta m^2 \simeq 10^{-5}$eV$^2$.

The direct implication of neutrino oscillations is the existence of non-zero neutrino masses in the eV range, and consequently a not negligible hot dark matter contribution to the total mass density of the universe (i.e. a density parameter $\Omega_\nu \neq 0$).

In view of the uncertainty in the direct neutrino experiments, a possible significant contribution can be obtained from the study of the cosmological implications of neutrino oscillations. In particular, the Cosmic Microwave Background (CMB) anisotropy pattern reflects the conditions in the universe at the time of the last scattering between photons and electrons, occurring at a redshift $z \approx 1000$ for standard recombination models. This means that all the physical processes occurring before this epoch could have left imprints on the CMB angular power spectra.

The standard Cold Dark Matter (CDM) model normalized to COBE/DMR data (Smoot et al. 1992, Wright et al. 1994, Górski et al. 1994, Bennet et al. 1996a) predicts both the amplitude and the shape of the CMB power spectrum at small scales consistent with the observations of the Large Scale Structure (LSS) of the universe as derived by galaxy surveys (e.g. Scott & White 1994; White et al. 1995; Primack et al. 1995). Recent works (Primack 1998; Gawiser & Silk 1998) show that the Cold + Hot Dark Matter (CHDM) model is the single model with $\Omega_m = 1$ whose predictions agree with both LSS observations and current CMB anisotropies data. The $\Omega^2$DM model (Primack et al. 1995) with two 2.4eV neutrinos contributing with 20% to the total density of the universe and with another 80% contribution from cold dark matter and a small baryon fraction, agrees remarkably with all available observations only if the Hubble parameter is $H_0 = 50$ km s$^{-1}$Mpc$^{-1}$ ($h_0 = H_0/100$ km s$^{-1}$Mpc$^{-1}$ = 0.5).

However, increasing evidence for larger value of the Hubble parameter, $h_0 \simeq 0.6 - 0.8$, (see e.g. Fukugita, Liu & Sugiyama 1999 and the references therein) are inconsistent with standard CHDM models. Such high values of the Hubble parameter make an $\Omega_m = 1$ universe suspiciously young unless the cosmological constant is non-zero. A way to improve the agreement of the standard CHDM models with eV neutrino mass with high values of Hubble parameter is to consider the relic neutrino degeneracy (the degeneracy parameter is defined as: $\xi_\nu = \mu_\nu / T_\nu$, where $\mu_\nu$ is the neutrino chemical potential and $T_\nu$ is the neutrino temperature), that enhances the contribution of neutrinos to the total energy density of the universe (Larsen & Madsen 1995). The cosmological implications of the neutrino degeneracy has been often considered in the literature: it can change the neutrino decoupling temperature (Freese et al. 1983; Kang & Steigman 1992), the abundances of light elements at the big bang nucleosynthesis (BBN) (Steigman et al. 1977; Kang & Steigman 1992), the CMB anisotropies and the matter power spectrum (Kinney & Riotto 1999). For the CHDM models with degenerated neutrinos, the increase of the neutrino chemical potential increases the effective number of neutrino species in the relativistic era (Larsen & Madsen 1995, Hamelestat 2000), and can bring the power spectral shape parameter in the range required by observations [for CDM models with low baryonic content the power spectral shape parameter (which basically measures the horizon scale at matter-radiation equality) is defined as (Dodelson et al. 1994); $\Gamma \approx \Omega_m h_0(g_*/3.36)^{-1/2}$, where $g_*$ counts the relativistic degrees of freedom and $g_* = 3.36$ corresponds to the standard model with photons and three massless neutrino species; observations require $0.22 < \Gamma < 0.29$]. The free-streaming properties of degenerated neutrinos also differ: when the neutrino chemical potential is increased, the neutrino number density is higher, although the neutrino energy density and the mean momentum change a little. The effect is the increase of the radiation energy density and the delay of the matter-radiation equality. It is shown (Larsen & Madsen 1995) that an $\Omega_m = 1$ CHDM model with one 2.4eV neutrino and $h_0 = 0.7$ is in good agreement with the observed LSS power spectrum of density fluctuations if the neutrino degeneracy parameter is $\xi_\nu \approx 2.8$. Constraints on neutrino degeneracy coming from BBN (Kang & Steigman 1992) indicate $-0.6 \lesssim \xi_\nu \lesssim 1.1$ and $|\xi_\nu| \lesssim 6.9$. Recent works (Pal & Kar 1999; Lesgourgues & Pastor 1999; Kinney & Riotto 1999, Lesgourgues et al. 2000) derive bounds on neutrino degeneracy parameter in agreement with BBN predictions, by combining the current observations of the CMB anisotropies and LSS data. The likelihood analysis of the CMB anisotropy data obtained by the Boomerang experiment indicates bounds on massless neutrino degeneracy parameter (Hamelestat 2000) of $|\xi_\nu| \lesssim 3.7$ if only one massless neutrino species is degenerated and $|\xi_\nu| \lesssim 2.4$ if the asymmetry is equally shared among three massless species. On the other hand, evidences has been accumulated that we live in a low matter density universe (see e.g. Fukugita, Liu & Sugiyama 1999 and the references therein). Indications like Hubble diagram of Type Ia supernovae (Riess et al. 1998, Perlmutter et al. 1998) and the acoustic peak distribution in the CMB anisotropy power spectra (Hancock et al. 1998, Efstathiou et al. 1999) point to a universe dominated by vacuum energy (cosmological constant $\Lambda$) that keeps the universe close to flat. The combined analysis of the latest CMB anisotropy data and Type Ia supernovae data (Efstathiou et al. 1999) indicates $\Omega_m = 0.25^{+0.12}_{-0.16}$ and $\Omega_\Lambda = 0.63^{+0.17}_{-0.23}$ (95% confidence errors) for matter and vacuum energy densities respectively. These values are close to those favoured by other arguments (see e.g. Efstathiou et al. 1999 and the references therein) like the ages of globular clusters, observations of large scale structure, baryon abundance in clusters.

Adding a Hot Dark Matter component to the ACDM model (ΛCDM) leads to a worse fit to LSS and CMB data, resulting in a limit on the total neutrino mass (Gawiser 2000) of $m_\nu \leq 2$eV for a primordial scale invariant power spectrum and $m_\nu \leq 4$eV for a primordial scale free power spectrum. A stronger upper limit is obtained (Fukugita, Liu & Sugiyama 1999) from the matching condition of the LSS power spectrum normalization $\sigma_8$ (defined as the $rms$ amplitude of the galaxy power spectrum in a sphere of radius $8h_0^{-1}$Mpc) at the COBE scale and at the cluster scale. For the case of a ΛCDM model having $\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$, and a primordial scale invariant power spectrum, it is found an upper limit of the total non-degenerated neutrino mass of $m_\nu < 0.6$ if the Hubble constant $H_0 < 80$ Km s$^{-1}$ Mpc$^{-1}$. 
In this paper we study the signature of relic degenerated neutrino oscillations on the CMB anisotropy and polarization power spectra and address its detectability with the future CMB anisotropy space missions, MAP (Microwave Anisotropy Probe) (see Bennet et al. 1996b) and PLANCK (Mandolesi et al. 1998, Puget et al. 1998). We consider the impact of neutrino oscillations in the epoch after nucleosynthesis. Neutrino oscillations are mediated by weak interactions: this fact implies that the order of magnitude of the interaction rate is less than the Hubble expansion rate after nucleosynthesis. In order to get an appreciable effect we consider a large neutrino asymmetry as left by processes occurred before and during nucleosynthesis. An example of such large asymmetries is given by considering a relic neutrino degeneracy (Larsen and Madsen 1995), which has been recently subject of renewed interest (Kinney and Riotto 1999; Lesgourges and Pastor 1999; Pal and Kar 1999). We analyze the oscillations of relic degenerated neutrinos under the simple assumption of oscillations occurring between two active neutrino flavors

\[ \nu_\mu \leftrightarrow \nu_\tau \quad \bar{\nu}_\mu \leftrightarrow \bar{\nu}_\tau \]

which have the following mass hierarchy:

\[ m_{\nu_\tau} = m_{\bar{\nu}_\tau} > m_{\nu_\mu} = m_{\bar{\nu}_\mu} \]

We assume the third neutrino \( \nu_e \) as massless and non-degenerate. We consider a total neutrino mass contribution of \( m_\nu = m_{\nu_\mu} + m_{\nu_\tau} = 0.6 \text{ eV} \) and a total neutrino degeneracy parameter \( \xi_\nu = |\xi_{\nu_\mu} + \xi_{\nu_\tau}| \leq 5 \) accordingly to the present observational data summarized above. We assume a scale invariant primordial power spectrum, the presence of the scalar modes with spectral index \( n_s = 1 \) and ignore the contribution of the tensorial modes and the reionisation effects. This model is consistent with the large scale structure and CMB anisotropy data, allowing in the same time a pattern of neutrino masses consistent with the results from atmospheric neutrino oscillations experiments.

In Section 2 we draw the basic formalism of the neutrino oscillation model necessary for understanding its impact on CMB angular power spectra. The features induced by the degenerated neutrino oscillations on the CMB anisotropy and polarization power spectra are presented in Section 3. In Section 4 we discuss the MAP and PLANCK capability of detecting neutrino oscillations. Finally, we summarize our main conclusions in Section 5. Throughout the paper we employ the system of units in which \( \hbar = c = k_B = 1 \).

### 2. Oscillations of degenerated neutrinos

The neutrino oscillations take place due to the fact that neutrino mass eigenstate components propagate differently because they have different energies, momenta and masses. In the standard assumption of the mixing of massive neutrinos, the neutrino flavor eigenstates are described by a superposition of the mass eigenstate components (Particle Data Group 1998). For oscillations occurring in vacuum between two neutrino flavors \( \nu_\mu \) and \( \nu_\tau \) the mixing can be written as:

\[
|\nu_\mu\rangle = \cos \theta_0 |\nu_2\rangle + \sin \theta_0 |\nu_3\rangle \\
|\nu_\tau\rangle = -\sin \theta_0 |\nu_2\rangle + \cos \theta_0 |\nu_3\rangle,
\]

where \( \nu_2 \) and \( \nu_3 \) are the mass eigenstate components and \( \theta_0 \) is the vacuum mixing angle. The mixing of antineutrinos can be obtained from equation (1) by performing the transformations \( \nu_\mu \leftrightarrow \bar{\nu}_\mu \) and \( \nu_\tau \leftrightarrow \bar{\nu}_\tau \). It is usual to consider that each neutrino/antineutrino of a definite flavor is dominantly one mass eigenstate (Particle Data Group 1998). In this circumstance we refer to the dominant mass eigenstate component of \( \nu_\mu/\bar{\nu}_\mu \) as \( \nu_2 \), that of \( \nu_\tau/\bar{\nu}_\tau \) as \( \nu_3 \) and to their difference of the squared masses as \( \Delta m^2 = m_3^2 - m_2^2 \).

The mixing of the mass eigenstate components are modified in the presence of the asymmetric background. The background mixing angle and the vacuum mixing angle are related through (see e.g. Foot et al. 1996):

\[ \sin^2 2\theta_m = \frac{\sin^2 2\theta_0}{1 - 2z \cos 2\theta_0 + z^2}. \]

Here \( z = 2 < p > < V_{\nu_i} > / \Delta m^2 \) \( (i = \mu, \tau) \), \( < p > \) is the averaged neutrino momentum and \( < V_{\nu_i} > \) is the neutrino effective potential due to the interaction with the asymmetric background (Enqvist et al. 1992; Foot et al. 1996):

\[ < V_{\nu_i} >= \sqrt{2} G_F n_\gamma \left( L^i - A_{\nu_i} \frac{p T_{\nu}}{4 M^2} [n_{\nu_i} + n_{\bar{\nu}_i}] \right), \]

### 3. Oscillations with Planck capability

In this paper we study the signature of relic degenerated neutrino oscillations on the CMB anisotropy and polarization power spectra and address its detectability with the future CMB anisotropy space missions, MAP (Microwave Anisotropy Probe) (see Bennet et al. 1996b) and PLANCK (Mandolesi et al. 1998, Puget et al. 1998). We consider the impact of neutrino oscillations in the epoch after nucleosynthesis. Neutrino oscillations are mediated by weak interactions: this fact implies that the order of magnitude of the interaction rate is less than the Hubble expansion rate after nucleosynthesis. In order to get an appreciable effect we consider a large neutrino asymmetry as left by processes occurred before and during nucleosynthesis. An example of such large asymmetries is given by considering a relic neutrino degeneracy (Larsen and Madsen 1995), which has been recently subject of renewed interest (Kinney and Riotto 1999; Lesgourges and Pastor 1999; Pal and Kar 1999). We analyze the oscillations of relic degenerated neutrinos under the simple assumption of oscillations occurring between two active neutrino flavors

\[ \nu_\mu \leftrightarrow \nu_\tau \quad \bar{\nu}_\mu \leftrightarrow \bar{\nu}_\tau \]

which have the following mass hierarchy:

\[ m_{\nu_\tau} = m_{\bar{\nu}_\tau} > m_{\nu_\mu} = m_{\bar{\nu}_\mu} \]

We assume the third neutrino \( \nu_e \) as massless and non-degenerate. We consider a total neutrino mass contribution of \( m_\nu = m_{\nu_\mu} + m_{\nu_\tau} = 0.6 \text{ eV} \) and a total neutrino degeneracy parameter \( \xi_\nu = |\xi_{\nu_\mu} + \xi_{\nu_\tau}| \leq 5 \) accordingly to the present observational data summarized above. We assume a scale invariant primordial power spectrum, the presence of the scalar modes with spectral index \( n_s = 1 \) and ignore the contribution of the tensorial modes and the reionisation effects. This model is consistent with the large scale structure and CMB anisotropy data, allowing in the same time a pattern of neutrino masses consistent with the results from atmospheric neutrino oscillations experiments.

In Section 2 we draw the basic formalism of the neutrino oscillation model necessary for understanding its impact on CMB angular power spectra. The features induced by the degenerated neutrino oscillations on the CMB anisotropy and polarization power spectra are presented in Section 3. In Section 4 we discuss the MAP and PLANCK capability of detecting neutrino oscillations. Finally, we summarize our main conclusions in Section 5. Throughout the paper we employ the system of units in which \( \hbar = c = k_B = 1 \).

### 2. Oscillations of degenerated neutrinos

The neutrino oscillations take place due to the fact that neutrino mass eigenstate components propagate differently because they have different energies, momenta and masses. In the standard assumption of the mixing of massive neutrinos, the neutrino flavor eigenstates are described by a superposition of the mass eigenstate components (Particle Data Group 1998). For oscillations occurring in vacuum between two neutrino flavors \( \nu_\mu \) and \( \nu_\tau \) the mixing can be written as:

\[
|\nu_\mu\rangle = \cos \theta_0 |\nu_2\rangle + \sin \theta_0 |\nu_3\rangle \\
|\nu_\tau\rangle = -\sin \theta_0 |\nu_2\rangle + \cos \theta_0 |\nu_3\rangle,
\]

where \( \nu_2 \) and \( \nu_3 \) are the mass eigenstate components and \( \theta_0 \) is the vacuum mixing angle. The mixing of antineutrinos can be obtained from equation (1) by performing the transformations \( \nu_\mu \leftrightarrow \bar{\nu}_\mu \) and \( \nu_\tau \leftrightarrow \bar{\nu}_\tau \). It is usual to consider that each neutrino/antineutrino of a definite flavor is dominantly one mass eigenstate (Particle Data Group 1998). In this circumstance we refer to the dominant mass eigenstate component of \( \nu_\mu/\bar{\nu}_\mu \) as \( \nu_2 \), that of \( \nu_\tau/\bar{\nu}_\tau \) as \( \nu_3 \) and to their difference of the squared masses as \( \Delta m^2 = m_3^2 - m_2^2 \).

The mixing of the mass eigenstate components are modified in the presence of the asymmetric background. The background mixing angle and the vacuum mixing angle are related through (see e.g. Foot et al. 1996):

\[ \sin^2 2\theta_m = \frac{\sin^2 2\theta_0}{1 - 2z \cos 2\theta_0 + z^2}. \]

Here \( z = 2 < p > < V_{\nu_i} > / \Delta m^2 \) \( (i = \mu, \tau) \), \( < p > \) is the averaged neutrino momentum and \( < V_{\nu_i} > \) is the neutrino effective potential due to the interaction with the asymmetric background (Enqvist et al. 1992; Foot et al. 1996):

\[ < V_{\nu_i} >= \sqrt{2} G_F n_\gamma \left( L^i - A_{\nu_i} \frac{p T_{\nu}}{4 M^2} [n_{\nu_i} + n_{\bar{\nu}_i}] \right), \]
where $A$ is a numerical factor ($A = 12.61$), $T$ is the neutrino temperature, $G_F$ is the Fermi constant ($G_F = 1.17 \times 10^{-11} \text{MeV}^{-2}$), $M_Z$ is the mass of the $Z$ boson, ($M_Z = 91.187 \text{GeV}$), $n_\gamma$ is the photon number density ($n_\gamma \simeq T^4/4.1$), $n_{\nu_\mu}$ and $n_{\bar{\nu}_\mu}$ are the neutrino and antineutrino number densities.

The equations are described by the set of functions

$$L_i = L_{\nu_i} + L_{\bar{\nu}_i} + L_{\nu_e} + L_{\bar{\nu}_e} + \eta \quad (i = \mu, \tau).$$

Here $\eta$ is approximately equal to the baryon to photon ratio, and $L_i$ are the lepton asymmetries defined as

$$L_i = \frac{n_\alpha - n_\bar{\alpha}}{n_\gamma},$$

where $n_\gamma$ are the number densities.

For the purpose of this work we consider large neutrino asymmetries ($L_{\nu_i} \geq 10^{-9}$). Also, we consider that $\nu_e$ is non-degenerated and consequently $L_{\nu_e} = 0$. In this case the functions $L_i$ may be written as

$$L_i \simeq L_{\nu_i} + L_{\bar{\nu}_i} + L_{\nu_e}.$$  

The effective potentials of antineutrinos can be obtained by replacing $L_i$ with $-L_i$ in equation (3).

The neutrino flavor eigenstates oscillate via weak interaction processes. The average oscillation probability $<P>_{\nu_i}$ of a flavor eigenstate $|\nu_i\rangle$ ($i = \mu, \tau$) is defined as (see e.g.: Raffelt 1996, Foot et al. 1996, Enqvist et al. 1992):

$$<P>_{\nu_i} = \sin^2 2\theta_m \left(\sin^2 \frac{L_{\nu_i}}{L_{\nu_e}} \Gamma_{\nu_i \rightarrow \nu_j}\right) \quad (i = \mu, \tau; j = \mu, \tau; i \neq j),$$

where $\Gamma_{\nu_i \rightarrow \nu_j}$ is the neutrino averaged elastic collision rate, $L_{\nu_i}$ is the mean distance between interactions (Foot et al. 1996), and the neutrino oscillation length $L_{\nu_e}$ is given by (see e.g. Raffelt 1996):

$$L_{\nu_e} = \frac{4\pi E_{\nu_i}}{\Delta m^2} \simeq 248\text{cm} \frac{E_{\nu_i}}{\text{MeV}} \frac{\text{eV}^2}{\text{MeV} \Delta m^2},$$

where $E_{\nu_i}$ is the neutrino energy. We will consider the $L_{\nu} \gg L_{\nu_e}$ and then $\langle \sin^2 (L_{\nu}/L_{\nu_e}) \rangle \rightarrow 1/2$ (Foot et al. 1996). The averaged collision rate is given by (Enqvist et al. 1992):

$$\Gamma_{\nu_i \rightarrow \nu_j} = 0.77G_F^2 \frac{T^5_{\nu_i}}{n_0},$$

where $n_0$ is the number density of massless non-degenerated neutrino species.

Equation (7) together with equations (2), (8), (9) gives the averaged oscillation probability $<P>_{\nu_i}$ used in the next section to evolve in time the neutrino distribution functions. The oscillation probabilities of antineutrinos can be obtained by performing the transformations $\nu_i \leftrightarrow \bar{\nu}_i$ and $\nu_j \leftrightarrow \bar{\nu}_j$ in equations (7) - (9).

3. CMB angular power spectra in the presence of neutrino oscillations

The phase space distribution functions of neutrinos and antineutrinos $f_{\nu_i}$ ($i = \nu_\mu, \bar{\nu}_\mu, \nu_\tau, \bar{\nu}_\tau$) are evolved independently, taking into account the redistribution of momenta due to oscillations and elastic collisions.

We describe the time evolution of the phase space distribution functions in the expanding universe by the set of equations:

$$\frac{\partial f_{\nu_i}(q)}{\partial t} = -<P>_{\nu_i} f_{\nu_i}(q) + <P>_{\nu_j} f_{\nu_j}(q), \quad (i = \mu, \tau; j = \mu, \tau; i \neq j)$$

$$\frac{\partial f_{\bar{\nu}_i}(q)}{\partial t} = -<P>_{\bar{\nu}_i} f_{\bar{\nu}_i}(q) + <P>_{\bar{\nu}_j} f_{\bar{\nu}_j}(q),$$

where $q = a$ is the comoving momentum (Ma & Bertschinger 1995), $p$ is the magnitude of the momentum 3-vector, $a$ is the scale factor ($a = 1$ today), $dt = da/(aH)$ and $H$ is the expansion rate:

$$H = \sqrt{\frac{8\pi G \rho_{\text{total}}(a)}{3}},$$

where $\rho_{\text{total}}$ is the total density of the universe.
where: $G$ is the gravitational constant and $\rho_{\text{tot}}(a)$ is the total energy density. The equations (10) assume that no other physical processes take place apart from oscillations and elastic collisions, leading to the conservation of the total neutrino/antineutrino number densities ($n_\nu/n_\bar{\nu}$) and degeneracy parameters ($\xi_\nu/\xi_\bar{\nu}$):

$$n_\nu = n_{\nu_i} + n_{\nu_j}, \quad n_\bar{\nu} = n_{\bar{\nu}_i} + n_{\bar{\nu}_j}, \quad (i = \mu, j = \tau)$$

$$\xi_\nu = \xi_{\nu_i} + \xi_{\nu_j}, \quad \xi_\bar{\nu} = \xi_{\bar{\nu}_i} + \xi_{\bar{\nu}_j}, \quad (i = \mu, j = \tau)$$

(12)

where $\xi_\alpha = \mu_\nu/\xi_\nu$ is the degeneracy parameter of the flavor $\alpha$ ($\alpha = \mu, \tau$) with the chemical potential $\mu_\alpha$, $\xi_\nu$ is the neutrino/antineutrino temperature and $|\xi_\nu| = |\xi_\bar{\nu}|$.

We have modified the CMBFAST code (Seljak & Zaldarriaga 1996) to take into account the evolution of the phase space distribution functions of neutrinos and antineutrinos at each value of the scale factor, by solving the set of equations (10). We start at the scale factor $a \simeq 10^{-3}$, when neutrinos and antineutrinos with the mass in eV range behave like relativistic particles with Fermi-Dirac phase space distributions:

$$f_\nu(q) = \frac{1}{e^{E_{\nu_i}/T_\nu} - \xi_\nu} + 1,$$

$$f_\bar{\nu}(q) = \frac{1}{e^{E_{\bar{\nu}_i}/T_\nu + \xi_\bar{\nu}} + 1}, \quad (i = \mu, \tau)$$

(13)

where $\xi_i$ is the degeneracy parameter, $E_{\nu_i} = \sqrt{q^2 + 4m^2_\nu}$ the neutrino/antineutrino energy, $m_\nu$ the dominant mass component of the flavor $i$, and $q$ the comoving momentum. The system of neutrinos and antineutrinos drops out of thermal equilibrium with $e^\pm$, photons, the small fraction of baryons and other massive species (e.g. $\mu^+\mu^-$ pairs) when the ratio of the averaged weak interaction rate to the expansion rate falls below unity. The decoupling temperature of degenerated neutrinos increases exponentially with the degeneracy parameter. For $\nu_\mu$ and $\nu_\tau$ the decoupling temperature is given by (Freese et al. 1983, Kang & Steigmann 1992) $T_D \simeq 10\text{ MeV} \xi^{-2/3} e^{(\xi/3)}$. The present values of neutrino/antineutrino temperature $T_{\nu}$ and photons temperature $T_0 = 2.725 \pm 0.002 \text{K}$ (Mather et al. 1999) are related through $T_{\nu}/T_0 \simeq (3.9/g_{*D})^{1/3}$ where $g_{*D}$ is the number of degrees of freedom in equilibrium at neutrino/antineutrino decoupling. For a degeneracy parameter $\xi_\nu \leq 15$, $T_D \simeq \text{few MeV}$ and the total number of relativistic degrees of freedom is $g_\ast \simeq 43/4$ (Freese et al. 1983). After the neutrino decoupling, the $e^+e^-$ pairs annihilate, heating the photons but not the neutrinos. From the entropy conservation one obtains that $T_{\nu0} \simeq (4/11)^{1/3} T_0$ and the total degeneracy parameter $\xi_\nu = \xi_{\nu_\mu} + \xi_{\nu_\tau}$ is considered constant.

We compute the mean energy density and pressure of each neutrino flavor as:

$$\rho_{\nu_i} + \rho_{\bar{\nu}_i} = \frac{T_{\nu}^4}{2\pi^2} \int_0^\infty dq \, q^2 E_{\nu_i} (f_{\nu_i}(q) + f_{\bar{\nu}_i}(q)), \quad (i = \mu, \tau)$$

$$P_{\nu_i} + P_{\bar{\nu}_i} = \frac{T_{\nu}^4}{6\pi^2} \int_0^\infty dq \, \frac{q^2}{E_{\nu_i}} (f_{\nu_i}(q) + f_{\bar{\nu}_i}(q)),$$  

(14)

the neutrino and antineutrino number densities:

$$n_{\nu_i} = \frac{T_{\nu}^4}{2\pi^2} \int_0^\infty dq \, q^2 f_{\nu_i}(q), \quad n_{\bar{\nu}_i} = \frac{T_{\nu}^4}{2\pi^2} \int_0^\infty dq \, q^2 f_{\bar{\nu}_i}(q), \quad (i = \mu, \tau)$$

(15)

and the present lepton asymmetry in the form of neutrinos (Kang & Steigmann 1992):

$$L_\nu = \sum_{i=\mu,\tau} \frac{1}{12\xi(3)} \frac{T_{\nu i}}{T_0} [\xi_{\nu_i} + \pi^2 \xi_{\bar{\nu}_i}].$$

(16)

We also compute at the beginning of the code the present value of neutrino parameter density:

$$\Omega_{\nu} = \sum_{i=\mu,\tau} \frac{(\rho_{\nu_i} + \rho_{\bar{\nu}_i})_{i=1}}{\rho_c},$$

(17)

where $\rho_c = 1.054 \times 10^4 h_0^2 \text{ eV cm}^{-3}$ is the critical density, and define the cold dark matter density parameter $\Omega_c = 1 - \Omega_b - \Omega_\nu - \Omega_\Lambda$. Following the same procedure used by the CMBFAST code, we compute in synchronous gauge the perturbations of the energy density, pressure, energy flux and shear stress (equations (52) – (56) from Ma & Bertschinger 1995) for neutrinos and antineutrinos of each flavor.
For all cases we indicate the corresponding values of \( \Omega \) and \( b \). We present (dashed lines) the CMB angular power spectra obtained for: \( \Omega \) in agreement with the CMB anisotropy power spectra presented by Lesgourgues & Pastor 1999. Also, in panels b1) and b2) we present (dashed lines) the CMB angular power spectra obtained for: \( \Omega \) exactly those obtained by using the unmodified version of the CMBFAST code.

Fig. 1. The dependence of CMB anisotropy (left panels) and polarization (right panels) power spectra on \( \Delta m^2 \) (panels a1) and a2) \( \sin^2 2\theta_0 \) (panels b1) and b2) \( \Delta \xi_\nu \) (panels c1) and c2) for a CHDM model having: \( \Omega_b = 0.023, \Omega_\Lambda = 0.7, \Omega_c = 1 - \Omega_b - \Omega_\nu - \Omega_\Lambda, h_0 = 0.65, m_\nu = m_\nu + m_\nu = 0.6eV, \xi_\nu = \xi_\nu + \xi_\nu = 5. \) As a consistency test we present in panel a1) the CMB anisotropy power spectra obtained for degenerate neutrinos with: \( m_\nu = 0.07eV, \xi_\nu = 3 \) (dashed line), \( m_\nu = 0.07eV, \xi_\nu = 0 \) (dash-dotted line) and \( h_0 = 0.65, \Omega_b = 0.05, \Omega_\Lambda = 0.7, \Omega_c = 1 - \Omega_b - \Omega_\nu - \Omega_\Lambda. \) In panels b1) and b2) we present (dashed lines) the CMB angular power spectra obtained for: \( \Omega_\nu \approx 0.015, \xi_\nu = 0, \Omega_b = 0.023, \Omega_\Lambda = 0.7, \Omega_c = 0.262, h_0 = 0.65, \) one massless and two massive neutrino species (see also the text). We choose such values of neutrino oscillation parameters in order to clearly see the neutrino oscillation effects on CMB power spectrum.

We performed the computations of the CMB anisotropy and polarization power spectra starting with \( N_{q_{\max}} = 15 \) equispaced sampling points of the phase space distribution functions and truncating the Boltzmann hierarchies for massive neutrinos (see equation (54) from Ma & Bertschinger 1995) at \( l_{\max} = 15 \) for every \( q \) value. We then gradually increase these numbers until \( N_{q_{\max}} = 100 \) and \( l_{\max} = 50 \) for testing the numerical precision and obtaining a relative accuracy better than \( 10^{-3} \) for the models with oscillations and without oscillations.

Figure 1 presents the dependence of the CMB anisotropy and polarization power spectra on the neutrino difference of the squared masses \( \Delta m^2 \), the vacuum mixing angle \( \sin^2 2\theta_0 \) and the lepton asymmetry \( L_\nu \), obtained in a CHDM model having: \( \Omega_b = 0.023, \Omega_\Lambda = 0.7, \Omega_c = 1 - \Omega_b - \Omega_\nu - \Omega_\Lambda, h_0 = 0.65. \) For all cases we assume a total neutrino mass \( m_\nu = m_\nu + m_\nu = 0.6eV \) and a total neutrino degeneracy parameter \( \xi_\nu = \xi_\nu + \xi_\nu = 5. \) We also assume a primordial scale-invariant power spectrum, the presence of the scalar modes with spectral index \( n_s = 1 \) and a standard ionization history of the universe. All the power spectra are normalized to COBE/DMR four-Year data (Bunn & White 1997). Panels a1) and a2) present the CMB anisotropy and polarization power spectra for \( \sin^2 2\theta_0 = 0.8, \Delta \xi_\nu = \xi_\nu - \xi_\nu = 4 \) (\( L_\nu = 3.54 \)) and some values of \( \Delta m^2 \). Panels b1) and b2) show the same power spectra for \( \Delta m^2 = 0.24eV^2, \Delta \xi_\nu = 4, \) and some values of \( \sin^2 2\theta_0 \). Panels c1) and c2) present the CMB anisotropy and polarization power spectra for \( \Delta m^2 = 0.24eV^2, \sin^2 2\theta_0 = 0.45 \) and \( \Delta \xi_\nu/L_\nu = 0/2.03, 1/2.13, 3/2.88, 4/3.54. \) For all cases we indicate the corresponding values of \( \Omega_\nu \) (equation (17)). Without oscillations our power spectra are in agreement with the CMB anisotropy power spectra presented by Lesgourgues & Pastor 1999. Also, in panels b1) and b2) we present (dashed lines) the CMB angular power spectra obtained for: \( \Omega_\nu \approx 0.015, \xi_\nu = 0, \Omega_b = 0.023, \Omega_\Lambda = 0.7, \Omega_c = 0.262, h_0 = 0.65, \) one massless and two massive neutrino species. We check that our results match exactly those obtained by using the unmodified version of the CMBFAST code.

The power spectra presented in Figure 1 show two distinct features: a vertical shift of the \( C_l \) at large \( l \) (present in
Fig. 2. The evolution with the scale factor of the energy densities, relative to the critical density, of the various components, for the models presented in Figure 1. Panel a): $\sin^2 2\theta_0 = 0.8$, $\Delta \xi_\nu = 4$ ($L_\nu = 3.54$) and $\Delta m^2$: 0.24eV$^2$ (continuous lines), 0.2eV$^2$ (long-dashed lines), 0.12eV$^2$ (dashed lines), 0 (dott-dashed lines). Panel b): $\Delta m^2 = 0.24eV^2$, $\Delta \xi_\nu = 4$ ($L_\nu = 3.54$) and $\sin^2 2\theta_0$: 0, 0.23, 0.45, 1 (see also the text). Panel c): $\Delta m^2 = 0.24$, $\sin^2 2\theta_0 = 0.45$ and $\Delta \xi_\nu / L_\nu$: 4/3.54 (continuous lines), 3/2.88 (long-dashed lines), 1/2.13 (dashed lines), 0/2.03 (dott-dashed lines). Panels a1), b1) and c1) show the separate contributions from the two types of massive neutrinos (together with antineutrinos) for the same cases of the above panels. For all values of the scale factor, $\sum \Omega_i = 1$.

all panels) with the increasing of $\Delta m^2$, $\sin^2 2\theta_0$ and $\Delta \xi_\nu$ values, that results from the modification of neutrino free streaming scales, and an horizontal shift of the Doppler peaks to lower $l$ when $\Delta m^2$ and $\Delta \xi_\nu$ are increased, that results from the increase of the sound horizon at recombination. The horizontal shift of $C_l$ is not present in panels b1) and b2) because the variation of $\sin^2 2\theta_0$, with $\Delta m^2$ and $\Delta \xi_\nu$ kept fixed, does not change $\Omega_\nu$ and consequently the Hubble expansion rate is not changed. (see equations 14 and 15).

For a better understanding of these features, Figure 2 shows the evolution with the scale factor of the energy densities, relative to the critical density, of the various components, for the models presented in Figure 1. Panel a) presents the evolution with the scale factor of $\Omega_i$ for $\sin^2 2\theta_0 = 0.8$, $\Delta \xi_\nu = 4$ ($L_\nu = 3.54$) and some values of $\Delta m^2$. The same time evolution is presented in panel b) for $\Delta m^2 = 0.24eV^2$, $\Delta \xi_\nu = 4$ ($L_\nu = 3.54$) and some values of $\sin^2 2\theta_0$. In these cases, as consequence of the conservation of the Hubble expansion rate for all values of the scale factor, the time evolution of $\Omega_i$ do not changes with the variation of $\sin^2 2\theta_0$. Panel c) presents the evolution with the scale factor of $\Omega_i$ for $\Delta m^2 = 0.24$, $\sin^2 2\theta_0 = 0.45$ and some values of $\Delta \xi_\nu / L_\nu$. Panels a1), b1) and c1) show the separate contributions from the two types of massive neutrinos for the same cases of the above panels. For all values of the scale factor, $\sum \Omega_i = 1$.

Figure 3 shows the time evolution (in synchronous gauge) of the perturbed energy density of the density field components. The left panels of Figure 3 present the evolution with the scale factor of the perturbed energy density of different density field components in the presence of neutrino oscillations ($\delta_{cdm}$ for CDM, $\delta_{bar}$ for baryons, $\delta_{rad}$ for radiation in the form of massless neutrino and photons, $\delta_{\nu_\mu}$ and $\delta_{\nu_\tau}$ for the massive neutrinos and antineutrinos, $\delta_{vac}$ for vacuum), for the models presented in Figure 1. Panel a) presents the evolution with the scale factor of $\delta_{cdm}$ for $\sin^2 2\theta_0 = 0.8$, $\Delta \xi_\nu = 4$ ($L_\nu = 3.54$) and some values of $\Delta m^2$. The same time evolution is presented in panel b) for $\Delta m^2 = 0.24eV^2$, $\Delta \xi_\nu = 4$ ($L_\nu = 3.54$) and some values of $\sin^2 2\theta_0$. In these cases, as consequence of the conservation of the Hubble expansion rate for all values of the scale factor, the time evolution of $\delta_{cdm}$ do not changes with the variation of $\sin^2 2\theta_0$. Panel c) presents the evolution with the scale factor of $\delta_{\nu_\mu}$ for $\Delta m^2 = 0.24$, $\sin^2 2\theta_0 = 0.45$ and some values of $\Delta \xi_\nu / L_\nu$. Panels a1), b1) and c1) show the separate contributions from the two types of massive neutrinos for the same cases of the above panels. For all values of the scale factor, $\sum \delta_i = 1$. The right panels of Figure 3 present, for the same mode $k$, the evolution with the scale factor of the quantity $\epsilon = \sigma_{\nu_1} - \sigma_{\nu_2}$ (proportional with the variation of the massive neutrinos shear stress), where $\sigma_{\nu_1}$ and
\[ \sigma_{\nu_1} = \sum_i \frac{\delta \rho_i}{\rho_i + P_i}, \quad \sigma_{\nu_2} = \sum_j \frac{\delta \rho_j}{\rho_j + P_j} \quad (i = \nu, \bar{\nu} \quad j = \nu, \bar{\nu}) \]  

Here \( \rho_\nu \) and \( P_\nu \) are the neutrino/antineutrino energy density and pressure and \( \delta \rho_\nu \) is the perturbation of neutrino/antineutrino energy density. For all cases the total neutrino mass is \( m_\nu = 0.6 \text{eV} \), the total neutrino degeneracy parameter is \( \xi_\nu = 5 \) and the cosmological model is the \( \Lambda \)CHDM model presented in Figure 1. In panels a1) and a2) of Figure 3 \( \sin^2 2\theta_0 = 0.8 \) and \( \Delta \xi_\nu = 4 \) are fixed, and \( \Delta m^2 = 0.24 \text{eV}^2 \) (continuous line) and \( \Delta m^2 = 0.12 \text{eV}^2 \) (dashed line). In panels b1) and b2) of the same figure \( \Delta m^2 = 0.12 \text{eV}^2 \) and \( \Delta \xi_\nu = 4 \) are fixed and \( \sin^2 2\theta_0 = 0.8 \) (continuous line), \( \sin^2 2\theta_0 = 0.23 \) (dashed line). We observe that the growth of \( \delta \rho_\nu \) is suppressed when \( \Delta m^2 \) and \( \sin^2 2\theta_0 \) values are increased, while the variation of neutrino shear stress gets larger with the increasing of these parameters. In panels c1) and c2) of Figure 3 \( \Delta m^2 = 0, \sin^2 2\theta_0 = 0 \) and \( \Delta \xi_\nu = 4 \) (continuous line) and \( \Delta m^2 = 0, \sin^2 2\theta_0 = 0 \) and \( \Delta \xi_\nu = 0 \) (dashed line). For this last case, \( \delta \rho_{\nu\mu} \approx \delta \rho_{\nu\tau} \) and \( |\epsilon| < 10^{-2} \).

**Fig. 3.** The evolution with the scale factor (in synchronous gauge) of the density perturbations (left panels) and of \( \epsilon = \sigma_{\nu_1} - \sigma_{\nu_2} \) (see also the text) for the mode \( k \approx 0.2 \text{Mpc}^{-1} \). Panels a1) and a2): \( \sin^2 2\theta_0 = 0.8, \Delta \xi_\nu = 4 \) and \( \Delta m^2 = 0.24 \text{eV}^2 \) (continuous line) and \( \Delta m^2 = 0.12 \text{eV}^2 \) (dashed line); Panels b1) and b2): \( \Delta m^2 = 0.12 \text{eV}^2, \Delta \xi_\nu = 4 \) and \( \sin^2 2\theta_0 = 0.8 \) (continuous line) and \( \sin^2 2\theta_0 = 0.23 \) (dashed line); Panels c1) and c2): \( \Delta m^2 = 0, \sin^2 2\theta_0 = 0, \Delta \xi_\nu = 4 \) (continuous line) and \( \Delta m^2 = 0, \sin^2 2\theta_0 = 0 \) (dashed line). For all cases the total neutrino mass is \( m_\nu = 0.6 \text{eV} \), the total neutrino degeneracy parameter is \( \xi_\nu = 5 \) and the cosmological model is the \( \Lambda \)CHDM model presented in Figure 1.

### 4. Detection of neutrino oscillations with CMB experiments

Different methods can be used to quantify the performance of a CMB experiment in measuring a given set of cosmological parameters. We estimate the errors on the oscillation parameters \( \Delta m^2 \) and \( \sin^2 2\theta_0 \) and the lepton asymmetry \( L_\nu \) by using the Fisher information matrix approximation, widely employed in the literature (e.g. Efstathiou & Bond 1999, Popa et al. 1999).

The Fisher information matrix elements \( F_{ij} \) measure the width and the shape of the likelihood function around its
maximum (Efstathiou & Bond 1999). The minimum error that can be obtained on a parameter \(s_i\) when we need to determine all parameters jointly, is given by:

\[
\delta s_i = \sqrt{F_i^{-1}},
\]

(19)
depending on the experimental parameter data set and the target model and the class of considered cosmological models.

If only the temperature anisotropy power spectrum \(C_Tl\) is used, the Fisher information matrix reads as (Efstathiou & Bond 1999):

\[
F_{ij} = \sum_l \frac{\delta \hat{C}_{Tl}}{\delta s_i} \cdot \text{Cov}^{-1}(C_{Tl}^2) \cdot \frac{\delta \hat{C}_{Tl}}{\delta s_j}.
\]

(20)

If both anisotropy and polarization power spectra are used, the Fisher information matrix is given by (Zaldarriaga & Seljak 1997a; Zaldarriaga 1997):

\[
F_{ij} = \sum_l \sum_{X,Y} \frac{\partial C_{Xl}}{\partial s_i} \text{Cov}^{-1}(\hat{C}_{Xl}, \hat{C}_{Yl}) \frac{\partial C_{Yl}}{\partial s_j},
\]

(21)

where: \(X\) and \(Y\) stands for \(T, E, C\) and \(B\) power spectra and \(\text{Cov}^{-1}\) is the inverse of the covariance matrix. For the purpose of this work we assume only scalar modes, then the relevant covariance matrix elements in equations (21) ÷ (23) are:

\[
\text{Cov}(\hat{C}_{Tl}^2) = \frac{2}{(2l+1)f_{\text{sky}}} (C_{Tl} + w_T^{-1} B_{Tl}^{-2})^2,
\]

\[
\text{Cov}(\hat{C}_{El}^2) = \frac{2}{(2l+1)f_{\text{sky}}} (C_{El} + w_E^{-1} B_{El}^{-2})^2,
\]

\[
\text{Cov}(\hat{C}_{Cl}^2) = \frac{2}{(2l+1)f_{\text{sky}}} [C_{Cl}^2 + (C_{Tl} + w_T^{-1} B_{Tl}^{-2})(C_{El} + w_E^{-1} B_{El}^{-2})],
\]

\[
\text{Cov}(\hat{C}_{Tl}\hat{C}_{El}) = \frac{2}{(2l+1)f_{\text{sky}}} C_{Tl} C_{El},
\]

\[
\text{Cov}(\hat{C}_{Tl}\hat{C}_{Cl}) = \frac{2}{(2l+1)f_{\text{sky}}} C_{Tl} C_{Cl},
\]

\[
\text{Cov}(\hat{C}_{El}\hat{C}_{Cl}) = \frac{2}{(2l+1)f_{\text{sky}}} C_{El} C_{Cl}.
\]

(22)

Here we set \(w_T = \sum_c w_T^c\) for anisotropy and \(w_P = \sum_c w_P^c\) for polarization (with the sum performed over detector channels), \(w_T^c = (\sigma_T^c \theta_{c,pix}^{-2})^{-2}\) and \(w_P^c = (\sigma_P^c \theta_{c,pix}^{-2})^{-2}\), where \(\sigma_T^c\) and \(\sigma_P^c\) are the relative noise per pixel for anisotropy and polarization channels (Knox 1995); \(B_{Tl}^2 = \sum_c B_{Tl,c}^2 w_T^c / w_T\) and \(B_{El}^2 = \sum_c B_{El,c}^2 w_E^c / w_E\) account for the beam smearing, \(B_{Tl,c}^2 = e^{-l(l+1)/l_s^2}\) is the Gaussian beam profile, \(l_s = \sqrt{8 \ln 2 (\theta_c f_{\text{whm}})^{-1}}\) and \(f_{\text{sky}}\) is the fraction of the sky used in the analysis.

Assessing PLANCK performances under realistic assumptions is a very delicate task: both instrumental systematic effects (e.g. Delabrouille 1998, De Maagt et al. 1998, Maino et al. 1999, Burigana et al. 1998 and references therein) and astrophysical contamination (e.g. Toffolatti et al. 1998,1999, De Zotti et al. 1999a,b and references therein) have to be carefully understood, reduced by optimizing the telescope (Mandolesi et al. 1998b) and the instrumental design (Bersanelli & Mandolesi 1998, Lamarre et al. 1998) and accurately subtracted in the data analysis. For simplicity, we consider only the MAP and PLANCK “cosmological windows”, i.e. those frequencies that are minimally affected by foregrounds contaminations, and neglect the degradation in CMB power spectrum recovering introduced by foreground contaminations and instrumental effects. As shown in Figure 4, in the cosmological channels extragalactic source fluctuations are comparable to CMB ones only at \(l > 10^3\), both for temperature (left panel) and polarization (right panel) anisotropies, whereas galactic fluctuations, which power spectrum overwhelms the extragalactic foreground one at \(l \lesssim 10^2\), are below the CMB ones at least far from the galactic plane.

Then, the possible imprinting of neutrino oscillations in the CMB anisotropy are not significantly masked from astrophysical contaminations at frequencies \(\sim 70 \pm 200\) GHz. We exploit then separately different sets of PLANCK
data: the “cosmological” LFI channels alone (70 and 100 GHz channels), the “cosmological” HFI channels alone (143 and 217 GHz channels and 100 GHz but for the temperature fluctuations only) and both together. For comparison, we consider also the set of data from the two MAP “cosmological” channels at 60 and 90 GHz. Table 1 lists the experimental parameters of the various experiments that we considered in our calculations.

Fig. 4. Temperature (left panel) and polarization (right panel) power spectra for the neutrino oscillation target model considered here (see also the text) compared to astrophysical component power spectra: the galactic temperature fluctuations at moderate galactic latitudes, sum of synchrotron, free-free and dust fluctuations, and the extragalactic source temperature fluctuations modelled as in Toffolatti et al. (1998) and De Zotti et al. (1999a) and the polarization fluctuations from galactic synchrotron and dust emission and separately from extragalactic radiosources and infrared sources modelled according to De Zotti et al. (1999b) and references therein. We report also the white noise nominal power spectrum for LFI and MAP, taking into account the effect of resolution loss at high $l$ due to the beam convolution.

The PLANCK and MAP data will be mainly used for determining the cosmological parameters; we exploit then the Fisher matrix method by evaluating together the uncertainties (1σ errors) of a simple set of cosmological parameters and of the parameters characterizing the neutrino oscillation model discussed here. As well known, the errors quoted for the considered parameters depend on the experiment sensitivity but also in part on the assumed target model and the set of considered parameters.

We assume as target model a spatially flat ΛCHDM model without oscillations having: $\Omega_b = 0.023$, $\Omega_\Lambda = 0.7$, $\Omega_c = 1 - \Omega_b - \Omega_\nu - \Omega_\Lambda$, $h_0 = 0.65$, $n_s = 1$, $m_\nu = m_\nu_\mu + m_\nu_\tau = 0.6\text{eV}$, $\xi_\nu = \xi_\nu_\mu + \xi_\nu_\tau = 5$, $\Delta \xi_\nu = 1$ ($L_\nu = 2.13$), $\Delta m^2 = 1.24 \times 10^{-2}\text{eV}^2$, and $\sin^2 2\theta_0 = 0$. We also assume a scale invariant power spectrum, the presence only of the scalar modes having a spectral index $n_s = 1$, and ignore the contribution of the tensorial modes and reionisation effects. The tensorial modes have a small contribution only to the polarization signal at low order multipoles (Crittenden & Turok 1995, Seljak 1997, Kamionkowski & Kosowsky 1998) that will be difficult to detect against the polarized foregrounds. Also, the reionisation effects can help in breaking the degeneracy only in the presence of the polarization signal for a large value of the optical depth to Thomson scattering (Zaldarriaga, Spergel & Seljak 1997).

We numerically compute the partial derivatives of the power spectra with respect to each relevant parameter $s_i$ by approximating them with the (possibly central) finite differences between the two power spectra obtained by varying with a quantity $\pm \Delta s_i/2$ the parameter $s_i$ in consideration around its value $s_{i,0}$ assumed in the considered
Clearly, the Planck peak number suffer the degeneracy between $\Omega_\Lambda$ of the power spectrum. Accurate evaluation of the derivative and large enough for having quite sensitive and numerically stable variations (see Efstathiou & Bond 1999 and the references therein) that imposes limits on the determination of $h_0$ and $\Omega_\Lambda$, and the correlations existing among the energy density parameters and $n_s$ and $\sin^2 2\theta_0$.

These errors can be understood in terms of the ability of each experiment to determine the properties of Doppler peaks (Efstathiou & Bond 1999): the location of the first Doppler peak and the positions, heights and relative amplitudes of the first and subsidiary Doppler peaks. The Doppler peak positions $d_A(z)$, $l_d \approx m\pi d_A(z)/r_s$, where $d_A(z)$ is the angular diameter distance to the last scattering, $r_s$ is the sound horizon distance and $m$ is the Doppler peak number] suffer the degeneracy between $\Omega_\Lambda$ and $h_0$ when $\Omega_m$ is fixed ($\Omega_m = \Omega_b + \Omega_c + \Omega_\nu = 0.3$). From equation (19) $\Omega_\nu$ value is given by the $\Delta m^2$ and $L_\nu$ values when the total neutrino mass is fixed, and therefore $\Delta m^2$ and $L_\nu$ are also correlated. The Doppler peak heights suffer the degeneracy between $\Omega_c$, $\Omega_b$, $\Omega_\nu$, $n_s$ and $\sin^2 2\theta_0$.

Clearly, the Planck LFI, probing the subsidiary Doppler peaks structure to high multipoles $l \sim 1500$, will produce a significant improvement with respect to MAP (sensitive up to $l \sim 1000$) in the determination of all parameters reducing their uncertainties. A further improvement can be achieved by exploiting the better sensitivity and angular resolution (up to $l \sim 2000$) of Planck HFI, the full Planck performance at very high $l$ being limited essentially by the foreground contamination.

On the other hand, other kinds of astronomical observations provide information on the cosmological parameters, complementary to those derived from CMB anisotropies. Galaxy cluster observations limit the shape parameter $\Gamma$ and the normalization of the galaxy power spectrum $\sigma_8$ and, combined with the galaxy peculiar velocity fields, provide information on the matter density in the universe $\Omega_m$ (Dekel 1994, Strauss & Willick 1995). Weak gravitational lensing provides also direct estimates of $\Omega_b$ (see e.g. Seljak 1998). The ratio between baryon and total mass in clusters $\Omega_b/\Omega_m \approx (0.01 - 0.02) h_0^{-1}$ (see e.g. Dodelson et al. 1996 and the references therein), informations from the BBN ($\Omega_b = 0.02 h_0^{-2}$ (Burles & Tytler 1998)) and the Helium Lyman-alpha Forest (Wadsley et al. 1999) constrain $\Omega_m$ or $h_0$ if $\Omega_m$ is known from other kinds of measurements. The complementarity between Type Ia supernovae luminosity distances and CMB anisotropy provides a powerful tool in breaking the degeneracy between $\Omega_c$ and $\Omega_\Lambda$ (see e.g. Perlmutter et al. 1998, Efstathiou & Bond 1999, Efstathiou 1999 and the references therein). The ages of the oldest globular clusters set lower limits on the age of the universe (see e.g. Chaboyer et al. 1998) and then on $\Omega_k$ and $\Omega_\Lambda$ if $\Omega_m$ is well constrained. For a spatially flat universe this contributes to break the geometrical degeneracy in $h_0 - \Omega_\Lambda$ plane. For CDM models with known baryonic content, measurements of $\Gamma$ from large scale structure, combined with independent determinations of $\Omega_m$, provide estimates on $h_0$ (Efstathiou & Bond 1999). Constraints on the scalar spectral index $n_s$ can be inferred also from limits on the primordial black hole abundance (Green, Liddle, & Riotto 1997) and on the CMB spectral distortions (Hu, Scott, & Silk 1994).

Recent CMB anisotropy measurements from Boomerang and MAXIMA-1 have been in fact used jointly to other astronomical observations to determine cosmological parameters through the so-called analysis with prior (Lange et al. 2000, Balbi et al. 2000). Of course, adding informations from other kind of observations helps both in circumventing the degeneracy problem and in improving the accuracy in the determination of the cosmological parameters.

Such a kind of analysis is out of the aim of this work. We just estimate here lower limits on the MAP and Planck sensitivity in determining the neutrino oscillation parameters, by exploiting the Fisher matrix method, assuming that all the cosmological parameters are known and estimating only the joint errors on $\Delta m^2$, $\sin^2 2\theta_0$, and $L_\nu$ that can be obtained from CMB anisotropy plus polarization data.

Table 3 presents these errors (1$\sigma$ errors) for Planck (LFI and HFI together) and MAP experiments; together with the results shown in Table 2, it provides a range of Planck and MAP sensitivity to neutrino oscillation parameters. Of course, in this case we find a significant reduction of the errors on the neutrino oscillation parameters for both Planck and MAP. These values can be also considered as estimates of lower limits on the errors on the neutrino oscillation parameters, as they could be in principle stetted by Planck and MAP experiments.

Figure 5 presents few confidence regions of the neutrino oscillation parameters space that can be potentially detected by the Planck surveyor and few allowed regions of $\Delta m^2$ and $\sin^2 2\theta_0$ at the same confidence level (CL) obtained by MACRO Collaboration (Ambrosio et al. 1998). According to the standard $\chi^2$ method (see e.g Particle Data Group 1998) an input model defined by the parameters
$(\Delta m^2, \sin^2 2\theta_0)$ is more likely to have occurred higher is the probability to obtain $\chi^2$ values larger then a specific value $\chi^2_0$. The cumulative probability that defines a certain confidence region on the parameters is given by:

$$CL(\chi^2_0) = \int_{\chi^2_0}^{\chi^2_{max}} L(\chi^2, \Delta m^2, \sin^2 2\theta_0) d\chi^2,$$

(23)

where $\chi^2_0 = \chi^2_{min} + \Delta \chi^2$, with $\Delta \chi^2 = 4.61, 9.21$ at 90% and 99% CL respectively (for a $\chi^2$ distribution with two degrees of freedom). The likelihood function in the equation (25) is defined as (Efstathiou & Bond 1999):

$$-2\ln \left( \frac{L}{L_{max}} \right) = \sum_{l<l_{max}} \frac{(C_l(s) - C_l(s0))^2}{\text{Cov}(C^2_l)},$$

where $C_l(s_0)$ is the power spectrum for the target model, $C_l(s)$ is the power spectrum for the input model having the same cosmological parameters as the target model and $\Delta m^2$ and $\sin^2 2\theta_0$ are in the intervals $(0 - 0.36)\text{eV}^2$ and $(0 - 1)$ respectively.

Panel a) of Figure 5 presents the confidence regions that could be obtained with the PLANCK surveyor for different fractions of sky. The target model is the $\Lambda CHDM$ model used in the previous section. Panel b) of the same figure presents the confidence regions obtained with PLANCK for $f_{sky} = 0.65$ and the same target model and for another target model.

In each panel we also present the allowed regions of $\Delta m^2$ and $\sin^2 2\theta_0$ as derived from the MACRO experiment. We conclude that exists a significant overlap between the region of the oscillation parameter space that can be potentially detected by PLANCK surveyor and that implied by the atmospheric neutrino oscillations data.

![Fig. 5.](image-url)

Fig. 5. Confidence regions of the neutrino oscillation parameter space that can be potentially detected by PLANCK surveyor by using CMB anisotropy measurements. Panel a): the allowed confidence regions at 99% CL (A) and at 90% CL (B) obtained for $f_{sky} = 0.65$ (continuous lines) and $f_{sky} = 0.8$ (dashed lines). The target model has $\Delta m^2 = 1.24 \times 10^{-2}\text{eV}^2$ and $\sin^2 2\theta_0 = 0$ (see also the text). Panel b): the allowed confidence regions at 99% CL (A) and at 90% CL (B) for $f_{sky} = 0.65$. The target model has: $\Delta m^2 = 1.24 \times 10^{-2}\text{eV}^2$ and $\sin^2 2\theta_0 = 0$ (continuous lines) and $\Delta m^2 \approx 10^{-4}\text{eV}^2$ and $\sin^2 2\theta_0 = 0$ (dashed lines). In each panel we also present (dash-dotted lines) the allowed regions of $\Delta m^2$ and $\sin^2 2\theta_0$ at 99% CL (A1) and 90% CL (B1) measured by the MACRO experiment.
5. Conclusions
The imprint of relic degenerated neutrino oscillations on the Cosmic Microwave Background (CMB) angular power spectra is evaluated in a ΛCHDM model consistent with the structure formation theories, allowing in the same time a pattern of neutrino masses consistent with the atmospheric neutrino oscillations data. Under the assumption that the total neutrino mass is known, as derived by the galaxy redshift surveys (Hu et al. 1998), we show that oscillations occurring between two active degenerated neutrino flavors leave detectable imprints on the CMB anisotropy and polarization power spectra.

By using the CMB anisotropy measurements, we find that the relic degenerated neutrino oscillations can be detected by PLANCK surveyor at 1σ level if the present value of the lepton asymmetry is \( L_ν \geq 9.7 \times 10^{-2} \), the difference of the neutrino squared masses is \( \Delta m^2 \geq 2.91 \times 10^{-2} \text{eV}^2 \) and the vacuum mixing angle is \( \sin^2 2\theta_0 \geq 0.46 \), when we consider other cosmological parameters that simultaneously affect the CMB angular power spectra and a sky coverage of \( f_{\text{sky}} = 0.8 \). A slight improvement can be obtained by using the CMB anisotropy and polarization data.

Assuming that all the other cosmological parameters may be known from other kind of astronomical observations, we estimate lower limits on future CMB anisotropy and polarization experiment sensitivity in determining the neutrino oscillation parameters alone: as shown in Table 3, the errors on neutrino oscillation parameters decrease at least by a factor two with respect to the case in which no prior on cosmological parameters are assumed. These values provide estimates of lower limits on the errors on the neutrino oscillation parameters, as they could be in principle stetted by PLANCK and MAP experiments.

Finally, we compare the confidence regions of the neutrino oscillation parameter space that can be potentially detected by the PLANCK surveyor with the few allowed regions of \( \Delta m^2 \) and \( \sin^2 2\theta_0 \) obtained by MACRO Collaboration (Ambrosio et al. 1998). We find a significant overlap between the region of the oscillation parameter space that can be potentially detected by PLANCK.

Acknowledgements. We acknowledge the use of the CMBFAST Boltzmann code (version 2.4.1) developed by U. Seljak and M. Zaldarriaga. We gratefully thank the long-standing, very fruitful collaboration on PLANCK performances and on foregrounds with M. Bersanelli, L. Danese, G. De Zotti, D. Maino and L. Toffolatti. It is a pleasure to acknowledge K. Enqvist, G. Giacomelli, R. Lopez, M. Maris and G. Venturi for useful and constructive discussions on neutrino oscillations. We wish to thank the referee for constructive comments. Part of this work was supported by NATO-CNR Fellowship Programme.
