Abstract

The deconfinement phase transition in large-$N_c$ QCD is studied within the framework of an effective Polyakov-loop model, where the potential has a U(1) symmetry originating in the large-$N_c$ limit of a $Z_{N_c}$-symmetric model. At the critical temperature, the shape of the effective potential allows the existence of Q-balls as position-dependent fluctuations of the Polyakov loop. Q-balls with spherical or axial symmetry are numerically obtained from the equations of motion of the effective model under consideration. The physical properties of these non-topological solitons (mass, charge and size) are discussed, as well as their interpretation in terms of spinning “bubbles”, with various shapes, of deconfined matter surrounded by a confined environment.

I. INTRODUCTION

The phenomenology related to the deconfined phase of hadronic matter – the quark-gluon plasma – is nowadays a matter of intense investigations. From a theoretical point of view, the study of gauge theories at finite temperature is a challenging problem, while the QCD matter is or will be studied in heavy-ion collisions at RHIC, SPS, FAIR, and the LHC. Informations and relevant references on the topic can be found for example in [1].

For a given Yang-Mills theory at a nonzero temperature $T$, the Polyakov loop is defined as $L(T, \vec{y}) = P e^{ig \int_0^{1/T} d\tau A_0(\tau, \vec{y})}$, with $A_0$ the temporal component of the Yang-Mills field and $\vec{y}$ the spatial coordinates. As usual, $P$ is the path-ordering, $g$ is the strong coupling constant and units where $\hbar = c = k_B = 1$ are used. The Polyakov loop is actually such that $\langle L(T, \vec{y}) \rangle = 0$ ($\neq 0$) when the theory is in a (de)confined phase [2]. Since gauge transformations belonging to the center of the gauge algebra only cause $L(T, \vec{y})$ to be multiplied by an overall factor, it is tempting to conjecture that the confinement/deconfinement phase transition might be linked to the spontaneous breaking of a global symmetry related to the center of the considered gauge algebra. In the particular case of $SU(N_c)$, deconfinement might thus be driven by the breaking of a global $Z_{N_c}$ symmetry [3], with the following dimensionless order parameter

$$\phi = \frac{1}{N_c} \text{Tr}_c L. \quad (1)$$

Note that the color-averaged Polyakov loop $\phi$ will simply be called Polyakov loop in the following.

It is well known that the thermodynamic properties of pure gauge $SU(3)$ QCD can be studied by resorting to an effective scalar field theory where the potential energy density is $Z_3$-symmetric, with $e.g.$ the form [4] $U \propto -a_2 |\phi|^2 + a_4 |\phi|^4 + a_3 (\phi^3 + \phi^\ast 3)$, see also Refs. [5, 6]. It has further been proposed in [7] that, for an arbitrary number of colors, the potential energy density should be of the $Z_{N_c}$-symmetric form $U = a_2 |\phi|^2 + a_4 |\phi|^4 + a_{N_c} (\phi^{N_c} + \phi^{\ast N_c})$. Moreover, the large-$N_c$ scaling and the temperature-dependence of the thermodynamic observables severely constrain the coefficients $a_i$ at large $N_c$, as it has been shown in [8]. One then gets a potential that becomes $U(1)$-symmetric in the large-$N_c$ limit. The main results of [8] concerning the Polyakov-loop effective potential will be summarized in Sec. II.
Polyakov-loop-inspired approaches are a precious tool to understand the QCD phase diagram: We refer the interested reader to e.g. Refs. [9], where the Polyakov loop is both coupled to quark fields and responsible for an effective potential. A direction that has been less studied so far is to work beyond mean field approximation and let the Polyakov loop fluctuate thanks to a standard kinetic term of the form $\partial_\mu \phi \partial^\mu \phi^*$: Dynamical effects like hadronization through decay of the Polyakov loop [10, 11] or formation of plasma bubbles in heavy ion collisions [12] can then be studied. The plasma bubbles found in the above references are actually static and spherically symmetric solutions of the equation of motion associated to a given Polyakov-loop Lagrangian; they can be interpreted as a sphere of deconfined matter surrounded by a confined medium. One of the main goals of the present paper is to go a step further in this direction and show that spinning plasma bubbles, and more generally bubbles with axial symmetry, may also exist. Such bubbles can reasonably be imagined to form in non central heavy-ion collisions, where the incident nuclei have a relative angular momentum.

It should be pointed out that there exist alternative descriptions of the pure gauge theory which make use of the transverse particle concept, see e.g. [13–15]. Descriptions of the physical phenomenon based on the AdS/QCD correspondence principle are also available, see namely [16–18].

The paper is organized as follows: The model we use is presented in Sec. III. It is directly inspired from the large-$N_c$, U(1) symmetric, Polyakov loop potential presented in [8]. The advantage of a U(1) symmetry is that it allows in principle the existence of Q-balls. In general, Q-balls refer to regular, finite mass and localized classical solutions of a complex, self-interacting scalar field theory [19, 20]; they form non-topological solitons of the underlying equations. In the present context, these solitons will come out as natural solutions of the Polyakov loop equation of motion. Q-balls with spherical and axial symmetry will be found by numerical resolution of the Polyakov-loop equations of motion in Secs. IV and V respectively. Their interpretation in terms of bubbles of deconfined plasma will be discussed, as well as their main physical properties. The various solutions obtained are compared in Sec. VI, while a discussion of the possible extensions of the present results to finite-$N_c$ cases and concluding comments are given in Secs. VII and VIII.
II. POLYAKOV-LOOP LAGRANGIAN

According the arguments exposed in the introduction, an effective Lagrangian for a finite-temperature SU($N_c$) Yang-Mills theory should involve the Polyakov loop, which is seen as a complex scalar field, as well as a $Z_{N_c}$-symmetric potential, denoted $V_g$. In order to mimic at best known results in Yang-Mills theory, $V_g$ should be such that:

- The pressure $p_g = -\min_\phi(V_g)$ is proportional to $N_c^2 T^4$ at large $N_c$ and $T$ in order to recover asymptotically the Stefan-Boltzmann limit for a free gluon gas.

- The value of the Polyakov loop minimizing $V_g$ is $N_c$-independent at the dominant order [21]. Numerically, $|\phi_0| = 0$ in the confined phase, $>0$ in the deconfined phase, and tends toward unity at very large $T$.

- There exists a critical temperature $T_c$ above which the absolute minimum is nonzero, so that one has a first-order phase transition. $T_c$ has to be seen as a typical value for the deconfinement temperature in SU($N_c$) Yang-Mills theory since the deconfinement temperature appears to be $N_c$-independent up to corrections in $1/N_c^2$ [22]. According to previously obtained results, the norm of the Polyakov loop when $T \to T_c^+$ may be found between 0.4 and 0.6 [23, 24].

It has been shown in [8] that the potential

$$V_g = N_c^2 T^4 a(T) \left[ |\phi|^2 - 4|\phi|^4 \right] + \frac{l(T)^2 - N_c}{N_c} [8l(T)^2 - 1] (\phi^{N_c} + \phi^{N_c*})$$

has all the required features and is moreover such that it leads to numerical values of the pressure and of the Polyakov loop in excellent agreement with recent lattice data [23, 25], both for $N_c = 3$ and in the large-$N_c$ limit. This last limit is particularly interesting for our purpose since, when $N_c \to \infty$, $V_g$ becomes U(1)-symmetric and reads [8]

$$V_g(|\phi|, T) = N_c^2 T^4 a(T) |\phi|^2 (1 - 4|\phi|^2) \quad |\phi| \leq l(T),$$

$$+ \infty \quad |\phi| > l(T).$$

\[3\]
FIG. 1: Polyakov-loop potential $V_g(|\phi|, T_c)$ versus $|\phi|$ in the large-$N_c$ limit (dashed line); $V_g$ is given by (3) and (4). The potential used in our numerical calculations, that is (5), is also plotted for comparison with $\beta = 10$ and $C = C_{10} = 27$ according to (6) (solid line).

It is worth mentioning that $l(T_c) = 1/2$, $a(T_c) = 2/3$, and that, as expected in the case of a first-order phase transition, the two minima are degenerate at the critical temperature: $V_g(0, T_c) = V_g(1/2, T_c) = 0$. The shape of the potential at $T = T_c$ is shown in Fig. 1; it is the typical kind of shape for which soliton-like solutions exist, as we will show in the following.

Potential (4), becoming infinite once $|\phi|$ is large than some $T$-dependent value, is not very convenient for numerical applications such as those that are to be performed. Instead of using this last form, we will rather introduce the following potential

$$V_g(|\phi|, T_c) = \frac{2}{3} N_c^2 T_c^4 \left(|\phi|^2 - 4|\phi|^4 + C|\phi|^\beta\right), \quad (5)$$

which can be seen as a more tractable approximation of (4) at $T = T_c$, with a term in $|\phi|^\beta$ introduced to mimic the “wall” of (4). Generic values of $C$ can be considered, but the main emphasis will be put on the particular choice

$$C = C_\beta \equiv \frac{4|\phi_\beta|^4 - |\phi_\beta|^2}{|\phi_\beta|^\beta}, \quad \text{where } |\phi_\beta| = \sqrt{\frac{\beta - 2}{4\beta - 16}}. \quad (6)$$

It is such that potential (5) is still zero in its two degenerate minima, namely $|\phi| = 0$ and $|\phi| = |\phi_\beta|$. This second minimum tends toward $1/2$ when $\beta$ is arbitrarily large: (4) is then recovered as the limit of (5) when $\beta$ tends toward infinity. The potential (5) is shown in
Fig. 1 for $\beta = 10$ and $C = C_{10} = 27$ according to (6): One sees that, though not being an extremely accurate approximation of (4) when $|\phi| > 0.5$, it shares the same structure, and will presumably lead to qualitatively similar results, which is satisfactory for our mostly exploratory purpose. Note that $|\phi_{10}| = 0.58$ instead of $1/2$, but this is still acceptable if one considers values previously found in computations of the critical value of the Polyakov loop [24].

It should be pointed out that the replacement of the potential (2) by (5) introduces an extra conserved quantity related to the continuous symmetry (for instance the charge $Q$ defined in the following). The consequence of this will be commented in due course.

III. THE MODEL AND THE EQUATIONS

A. Reduced Lagrangian

We now consider that the Polyakov loop $\phi$ is a dynamical complex scalar field. According to the suggestion of e.g. Ref. [5], we take a kinetic part of the form $N_c^2 T^2 \partial_\mu \phi \partial^\mu \phi^*/\lambda$, which has both the correct energy dimensions and the expected $N_c$-scaling. $\lambda$ is the 't Hooft coupling. The starting Lagrangian, valid at $T = T_c$, is thus given by

$$L_{\text{phys}} = \frac{N_c^2 T^2}{\lambda} \partial_\mu \phi \partial^\mu \phi^* - \frac{2}{3} N_c^2 T^4 (|\phi|^2 - 4|\phi|^4 + C|\phi|^\beta),$$  \hspace{1cm} (7)

where $\phi = \phi(y^\mu)$, $y^\mu$ being the spacetime coordinates. It is natural to further define dimensionless variables $x^\mu$ related to the original (physical) ones by

$$y^\mu = l_{\text{phys}} x^\mu, \text{ with } l_{\text{phys}} = \frac{1}{T_c} \sqrt{\frac{3}{2\lambda}},$$  \hspace{1cm} (8)

so that the above Lagrangian can be replaced by

$$L = \frac{L_{\text{phys}}}{(2/3) N_c^2 T^4} = \partial_\mu \phi \partial^\mu \phi^* - V(|\phi|),$$  \hspace{1cm} (9)

where $\phi = \phi(x^\mu)$ and

$$V(|\phi|) = |\phi|^2 - 4|\phi|^4 + C|\phi|^\beta.$$  \hspace{1cm} (10)

The corresponding classical equations of motion read

$$\partial_\mu \partial^\mu \phi = \frac{\partial V}{\partial \phi^*} = \phi (1 - 8|\phi|^2 + \frac{\beta C}{2} |\phi|^\beta),$$  \hspace{1cm} (11)
plus the complex conjugated equation.

B. The ansatz for Q-balls and conserved quantities

The standard way to construct Q-balls consists in looking for solutions of the form

$$
\phi(x^\mu) = \exp(i\omega x^0)\psi(\vec{x}),
$$

(12)

where $\psi(\vec{x})$ is a function of the space variables. The real parameter $\omega$ constitutes an essential characterisation of the stationary solution. As will be soon discussed, solitons only exist for $\omega$ taking values in a finite interval.

Two types of solutions will be searched for: Spherically- or axially-symmetric ones. Spherically symmetric solutions correspond to further assuming $\psi(\vec{x}) = \chi(r)$, where $r$ is the radius in spherical coordinates. Axially symmetric solutions correspond to the ansatz $\psi(\vec{x}) = \exp(ik\varphi)\chi(r, \theta)$, where $\{r, \varphi, \theta\}$ denote the standard spherical coordinates and where $k$ is an integer. We remark that $\chi$ is assumed to be a real function.

The solutions we will build can be characterised by their energy $M$ and by a dimensionless conserved charge $Q$, respectively defined by

$$
M = M_{\text{phys}} \int d^3x \ T_{00}
$$

(13)

and

$$
Q = 2\omega \int d^3x \ |\phi|^2.
$$

(14)

The temporal component of the energy-momentum tensor represents the energy density, given by

$$
T_{00} = \omega^2|\phi|^2 + \vec{\nabla}\phi \cdot \vec{\nabla}\phi^* + V(|\phi|).
$$

(15)

The natural mass scale introduced above reads

$$
M_{\text{phys}} = \sqrt{\frac{3}{2} \frac{N_c^2 T_c}{\lambda^{3/2}}}. \quad (16)
$$

The conserved charge $Q$ finds its origin in the $U(1)$-symmetry of the considered lagrangian, leading to a conserved Noether current of the form $J_\mu = i(\partial_\mu \phi^* - \phi^* \partial_\mu \phi)$, $Q$ being the the space integral of $J_0$. Note that the axially symmetric solutions having $k \neq 0$ are spinning
Q-balls whose angular momentum $J$ is related to the charge $Q$ according to $J = kQ$ \cite{26}. This relation is specific to Q-balls: the solutions constructed with the potential (2) could still have a conserved angular momentum while $Q$ would be meaningless.

Let us point out that all the masses and lengths to be plotted below are expressed in units of $M_{\text{phys}}$ and $l_{\text{phys}}$ respectively.

\section{Physical quantities}

At this point we have to stress that the proposed model does not intend to provide an accurate description of “realistic” plasma bubbles that might form in heavy ion collisions. It is rather a first step to explore the different kinds of soliton-like solutions of a typical Polyakov-loop-inspired model of the QCD phase transition. Nevertheless, it has been shown in Ref. \cite{8} that our model correctly reproduces the QCD equation of state in the large-$N_c$ limit computed on the lattice \cite{25}, and leads to a commonly accepted shape for the QCD phase diagram once coupled to quarks. Therefore we think that the Q-balls we will obtain have something to tell, at least qualitatively, on non-trivial phenomena that might arise at the deconfinement temperature.

It is worth estimating here the physical mass and length used in the model thanks to some known numbers concerning the quark-gluon plasma at $N_c = 3$. First, a typical value for the deconfinement temperature in QCD is $T_c = 0.2$ GeV \cite{11}. Second, the ’t Hooft coupling can be expressed as a function of the strong coupling constant $\alpha_s$ through $\lambda = 4N_c\pi\alpha_s$. A way to estimate $\alpha_s$ is to note that the short-range part of the static interaction between a quark and an antiquark scales as $-(4/3)\alpha_s/r$, at least from $T = 0$ to $T_c$. Recent lattice studies, performed at $N_c = 3$ and with 2 light quark flavors, favor $\alpha_s = 0.2$ up to $T = T_c$ \cite{34}, that is the value we retain here. We are then in position to estimate that, at $N_c = 3$,

$$l_{\text{phys}} = 2.2 \text{ GeV}^{-1} = 0.44 \text{ fm}, \quad M_{\text{phys}} = 0.107 \text{ GeV}.$$ 

(17)
IV. SPHERICALLY SYMMETRIC SOLUTIONS

Starting from Lagrangian (10), the field equation reduces, in the spherically symmetric case, to the differential equation:

$$\frac{d^2\chi}{dr^2} + \frac{2}{r} \frac{d\chi}{dr} = \chi(1 - \omega^2 - 8\chi^2 + \frac{\beta C}{2} \chi^{\beta-2})$$  \hfill (18)

which has to be solved for \( r \in [0, \infty] \). The regularity of the solution at the origin implies \( d\chi(0)/dr = 0 \), the finiteness of the energy and the charge impose \( \chi(\infty) = 0 \). These conditions specify the conditions at the boundary.

Adapting the results of Ref. [26] to our potential, it can be shown that Q-balls with spherical symmetry exist for

$$\omega^2_\beta \leq \omega^2 \leq 1 \quad \text{with} \quad \omega^2_\beta = \min \{0, 1 - \frac{4\beta - 16}{\beta - 2} \left( \frac{8}{C (\beta - 2)} \right)^{\frac{2}{\beta - 2}} \}$$  \hfill (19)

In particular, \( \omega_\beta = 0 \) if \( C \leq C_\beta \). Only for \( C > C_\beta \) the lower bound is non-zero. The case mostly studied in Ref. [26, 27] corresponds (up to an appropriate renormalisation of the field and of the radial variable) to \( \beta = 6 \) and \( C = 44/10 \) so solutions exist for \( 1/11 < \omega^2 < 1 \). In the present work, we are mostly interested in the case \( C = C_\beta \) for which Q-balls exist for \( \omega \in [0, 1] \). For \( \beta = 6 \), i.e. the most commonly used value in studies devoted to Q-balls, we have \( C_6 = 4 \).

In order to calibrate our solutions with cases studied in the literature, we have first solved the equations for \( C = 44/10 \) and several values of \( \beta \). The mass \( M \) and charge \( Q \) of these solutions are reported as functions of \( \omega \) on Fig. 2 (left side). On the right side, the same quantities are reported for \( N = 10 \) and two values of \( C \): the value \( C = 44/10 \) corresponds to Ref. [26], and \( C = 27 = C_{10} \) is the case under consideration for this paper. We have checked that we recover indeed previously obtained solutions for the aforementioned values of the parameters.

It is worth saying that Eq. (18) has, to our knowledge, no analytic solution for arbitrary values of \( \beta \) and has to be solved numerically. We exclude of our considerations the trivial case \( C = \beta = 4 \), actually leading to a free Schrödinger equation for \( \chi \). It should be pointed out that even a numerical approach is not obvious because the boundary conditions are
FIG. 2: Left: Mass (solid lines) and charge (dashed lines) of spherically symmetric Q-balls for 
$C = 44/10$ and (from top to bottom) $\beta = 6, 8, 10$. Right: Idem for $\beta = 10$ and (from top to 
bottom) $C = 27, 44/10$.

compatible with the trivial solution $\chi(r) = 0$. As a consequence, obtaining a non trivial 
numerical solution requires a starting guess which is reasonably close to the desired solution. 
We used a collocation method for boundary-value ordinary differential equations, equipped 
with an adaptive mesh selection procedure \cite{28}. Our solution were constructed with a relative 
error of order $10^{-8}$.

In the following, we focus on the case $\beta = 10$ and $C = C_{10} = 27$. From a technical 
point of view, the numerical construction of the solutions, especially the axially symmetric 
one, becomes more involved while increasing $\beta$; that is why no values of $\beta$ large than 
10 will be used. Nevertheless we think that the case $\beta = 10$ already captures most of 
the qualitative features of the limit $\beta \to \infty$, that corresponds to our original Lagrangian. 
Solutions corresponding to $\omega = 0.1, 0.3, 0.6, 0.95$ are plotted in Fig. 3 in order to show the 
behaviour of $\chi(r)$ and $T_{00}(r)$ for various values of $\omega$ lying in the range $[0, 1]$.

For small values of $\omega$, the minimum of the effective potential is deep and the scalar 
field “likes” to stay close to this minimum: It can be observed in Fig. 3 that, confirming 
this observation, our numerical results demonstrate that the radial function $\chi(r)$ remains 
practically constant (i.e. $\chi(r) \sim \chi(0) \equiv |\phi_\beta|$) inside a large sphere centred at the origin.
Then it brutally decreases to the asymptotic value $\chi(r \to \infty) = 0$, forming a thin wall. Accordingly the energy density presents a plateau for $T_{00} = \omega^2 \phi^2$ inside the sphere, then reaches a maximum on a spherical shell corresponding to the wall and finally decreases to zero. These features appear on Fig. 3. The scenario is quite different for $\omega$ close to unity. Here the effective potential’s minimum is not deep anymore and the scalar field quickly reaches its asymptotic value as shown in Fig. 3. This is the thick-wall limit.

A question that is worth asking is: Does the Q-balls we have found describe some deconfined sphere – or spherical shell – surrounded by a confined environment? Although the Polyakov loop is a straightforward indicator of confinement in a mean-field treatment, this is less obvious in the present framework, where it is never exactly zero, unless asymptotically by construction. We find that a good criterion could be instead given by the value of the energy density. According to the recent lattice computations of the pure gauge QCD equation of state given in [25], one can estimate that the deconfined phase is characterised by energy densities such that $\epsilon \geq 0.35 N_c^2 T_c^4$. By recalling that $\epsilon = T_{00} M_{phys} / \ell_{phys}^3$, we can
translate the criterion \( \epsilon \geq 0.35 \) into

\[ T_{00} \geq 0.45. \quad (20) \]

This last inequality can be used in the following as a criterion to separate the confined regions from the deconfined ones in the solutions we find. A glance at Fig. 3 shows that only Q-balls with \( \omega > 0.6 \) show deconfined regions according to the above criterion. Only these Q-balls could then be interpreted as “plasma balls” or “plasma shells”, while the others would just be fluctuations of the Polyakov loop in a completely confined region of space. As it can be observed in the left panel of Fig. 2, Q-balls with \( \omega \) around 0.9 not only contain a deconfined part, but are also the lightest ones that can be obtained. The Q-ball with minimal mass is reached for \( \omega = 0.88 \), with a charge \( Q = 13.7 \) and a mass \( M = 14.7 \) (1.57 GeV). In the thick-wall limit, that is for \( \omega = 1 \), one has finally \( Q = 55.0 \) and \( M = 55.2 \) (5.87 GeV). We mention finally that the Q-ball with \( \omega = 0.6 \) has a charge \( Q = 44.5 \) and a mass \( M = 35.5 \) (3.78 GeV).

V. AXIALLY SYMMETRIC SOLUTIONS

Let us now turn to axially symmetric solutions. To our knowledge, they have never been obtained so far within the framework of a Polyakov-loop model or, more technically, in a Q-ball study using the value \( \beta = 10 \). The field equation reads in this case

\[
\frac{\partial^2 \chi}{\partial r^2} + \frac{2}{r} \frac{\partial \chi}{\partial r} + \frac{1}{r^2} \frac{\partial^2 \chi}{\partial \theta^2} + \frac{\cos \theta}{r^2 \sin \theta} \frac{\partial \chi}{\partial \theta} - \frac{k^2}{r^2 \sin^2 \theta} \chi = \chi(1 - \omega^2 - 8 \chi^2 + \frac{\beta C}{2} \chi^{\beta-2}), \quad (21)
\]

and has to be solved in principle for \( r \in [0, \infty] \) and \( \theta \in [0, \pi] \). The above equation is notoriously difficult to solve because it is an elliptic non-linear partial differential equation. It has to be completed by appropriate boundary conditions which are given below. However, rendering the numerical construction more difficult, the different sets of conditions are compatible with the trivial solution \( \chi(r, \theta) = 0 \). Several solutions of equations of the type above were constructed in different contexts, see e.g. [29–31]. Comparisons of these solutions with ours constitutes a useful crosscheck of our numerical method. For our problem, the integration was performed numerically by a routine [32] based on the Newton-Raphson method. Concerning the angular dependence of the solutions, we will focus on Q-balls which are even
or odd under the reflection $\theta \to \pi - \theta$. Accordingly the interval of the variable $\theta$ can be limited to $\theta \in [0, \pi/2]$. In addition to their mass and charge, the solutions with $k > 0$ are further characterized by an angular momentum given by $J = kQ$ (see [26] for details).

A. Spinning solutions

Setting $k = 1$, Eq. (21) can be solved by imposing the boundary conditions

$$
\chi(0, \theta) = 0 \ , \ \chi(\infty, \theta) = 0 \ , \ \chi(r, \theta = 0) = 0 \ , \ \partial_{\theta}\chi(r, \theta = \pi/2) = 0. \tag{22}
$$

Solutions of this type are even under the reflexion $\theta \to \pi - \theta$ and have angular momentum $J = Q$. Such Q-balls have been first obtained in [26] for $\beta=6$; they can be deformed to the case of our potential. As an illustration, plots of the function $\chi(r, \theta)$ and of the region where the energy density satisfies to the criterion (20) are presented in Fig. 4 for the solution $\omega = 0.8$. It is readily seen that the spinning Q-ball found by applying the boundary conditions (22) has a toric shape, winding and spinning around the $z$-axis. Such a Q-ball may be seen as a “plasma ring”: A spinning torus of deconfined matter. Note that all the values of $\omega$ for which we have found a solution show a similar toric shape and a deconfined part.

A more accurate description of the $\chi$ field and of the energy density in the equator plane is presented in Figs. 5 for several values of $\omega$. We were able to construct solutions for $\omega \in [0.55, 0.99]$. The upper limit for $\omega$ is the same as in the spherically symmetric case as it has previously been observed in [27]. It is likely that solutions exist also for smaller $\omega$ but their construction become highly involved and understanding in detail the full pattern of solutions is not the aim of this exploratory work. The numerical difficulties in obtaining solutions for small $\omega$ are recurrent and also pointed out in [27]. In the case of spherically symmetric solutions, it turns out that several solutions exist with the same $\phi(0)$ and different $\omega$, the values of $\phi(0)$ becoming weakly dependant on $\omega$. In the case of axial solutions, the difficulty seems to be related to the fact that the solution spreads over spacetime and the mesh has to be updated constantly. At least, the spinning solution with the minimal energy occurs inside the interval that we explored and is reached for $\omega \approx 0.86$ where $M \approx 55$ (5.9
FIG. 4: Left: Plot of the scalar field function in the $\phi = 0$ plane for the spinning Q-balls with boundary conditions corresponding to $\beta = 10$, $C = C_{10} = 27$ and $\omega = 0.8$. Right: Plot of the region where $T_{00} \geq 0.45$ for the same solution. Note that $\{x, y, z\}$ denote standard cartesian coordinates.

GeV) and $Q \approx 51$. The largest diameter of the deconfined part in this lightest solution is about 8, that is around 3.5 fm.

**B. Further axial solution**

The angular dependence of the spherically symmetric and spinning solutions discussed above have the same symmetries as the $Y_0^0$ and $Y_1^1 \propto \sin(\theta)$ spherical harmonics. It is therefore tempting to assume that families of solutions exist with the symmetries of the $Y_m^k(\theta, \phi)$ spherical harmonics with $-m \leq k \leq m$. For instance the parity-odd spinning solution of has the same angular symmetries as the function $Y_2^1$. According to this observation there should exist also within our framework a family of solutions related to e.g. the function $Y_1^0 \propto \cos(\theta)$. Such solutions were first constructed in with $\beta = 6$ and different values for the parameter $C$, and here checked to exist for generic values of the potential’s parameters.
FIG. 5: Left: Energy density in the equator plane for the spinning Q-balls with boundary conditions \[ \text{(22)} \], \( N = 10 \) and \( C = C_{10} = 27 \) for several values of \( \omega \). From top to bottom: \( \omega = 0.8, 0.7, 0.6 \) (solid lines) and \( \omega = 0.9, 0.95, 0.99 \) (dashed lines). Right: Idem for the field \( \chi(r, \pi/2) \) with, from left to right, \( \omega = 0.8, 0.7, 0.6 \) (solid lines) and \( \omega = 0.9, 0.95, 0.99 \) (dashed lines).

Configurations with the \( Y_1^0 \) angular dependence can be obtained with \( \beta = 10 \) and \( C = 27 \) as Q-ball solutions of Eq. \[ \text{(21)} \] and the boundary conditions

\[ \chi(0, \theta) = 0 , \quad \chi(\infty, \theta) = 0 , \quad \partial \chi(r, \theta = 0) = 0 , \quad \chi(r, \theta = \pi/2) = 0. \quad (23) \]

These boundary conditions ensure the solution to be odd under parity. We are able to construct with a good accuracy the branch of solutions for \( \omega \in [0.55, 0.95] \). On this interval a configuration with minimal mass seems to be reached for \( \omega \approx 0.92 \), corresponding to \( M \approx 26 \) (2.8 GeV). As an illustration, the solution obtained for \( \omega = 0.8 \) is plotted in Fig. 6.

The norm of the \( \chi \)-field and the energy density are concentrated in two regions of the \( z \)-axis, say around \( z = \pm z_c \): We find \( z_c \approx 6 \) (2.6 fm) for \( \omega = 0.8 \). Such Q-balls could be seen as a two-center deconfined region, much like a bound state of two “plasma bells”.

The evolution of the energy density on the (positive) \( z \)-axis for different values of \( \omega \) can be estimated from Fig. 7. It suggests that the structure of the lump may become quite involved when \( \omega \) decreases. Again, the construction of such low-\( \omega \) Q-balls has not been undertaken, and deconfined regions appear for all the considered values of \( \omega \).
VI. COMPARISON AND STABILITY

To complete the description of the different solutions just found, we report their mass and charge as functions of the parameter $\omega$ on the left panel of Fig. 8. This part of the figure is limited to $\omega \in [0.6, 0.95]$, where the three types of solutions have been constructed. Likely due to the large exponent of the field $\beta = 10$, the numerical resolution of the partial differential equation (21) becomes unreliable for $\omega < 0.6$; a more appropriate discretisation of the space of integration would probably do the job. However, as stated above, we have been able to obtain the solutions with the lowest energy, that are the most likely to be produced at the deconfinement phase transition. Let us label the different branches of solutions by the couple $(m, k)$ according to their angular dependence in relation with the $Y^k_m$ spherical harmonic. As expected, for fixed $\omega$, the solution with the lowest energy is the spherically symmetric solution, then come successively the axially symmetric $(1,0)$ and the spinning $(1,1)$ solution.
FIG. 7: Field (solid lines) and energy density (dashed lines) on the positive z-axis for the Q-balls with boundary conditions (23), $\beta = 10$ and $C = C_{10} = 27$ for different values of $\omega$: From left to right, $\omega = 0.6, 0.75, 0.9, 0.95$. The corresponding values on the negative z-axis may be obtained by recalling that $\chi(T_{00})$ is an odd (even) function of $z$.

Perhaps more relevant is the right panel of Fig. 8 which represents a $(Q, M)$ plot of the different solutions. As observed in [27] for example, it reveals that, for each family $(m, k)$, the curve $M(Q)$ presents different branches terminating into spikes at critical values of the charge. According to standard arguments based on bifurcation theory, the branch with the lowest energy should be stable while the branches with higher energy are unstable, see e.g. [35].

For all values of the conserved charge covered by our solutions, the solution with the lowest energy is a spherically symmetric solution. On the graph, this corresponds to the lowest branch. Note that the two lines corresponding to the spherical solution are plotted up to $Q = 200$ on the graph, but actually terminates with a spike at $Q \approx 2200$, $M \approx 806$ (the graph was cut for obvious reason).

For the values $Q > 55$, the two axially symmetric solutions coexist and it can be checked that the spinning solution always possesses the lowest mass at a given charge. In the region
FIG. 8: Left: Mass (solid lines) and charge (dashed lines) as function of $\omega$ of, from top to bottom, the spinning solution (1,1), the axial solution (1,0), and the spherical solution (0,0). Right: Mass versus charge of the different solutions obtained. A zoom on the region with the lowest masses and charges has been also added.

$27 < Q < 55$, the spinning solution does not exist and the second lowest mass is the (1,0) axial solution (corresponding to the red line). More details of this branch are shown in the window, which is a zoom of the plot on the low $Q$ and $M$ region. Comforting these results about the stability, obtained on the basis of the theory of bifurcations, let us finally point out that the various branches of stable solutions fulfil the condition $M < M_{\text{free}}$, $M_{\text{free}} = m_b Q$ where $m_b$ is the mass of the boson in the underlying field theory (with our units $m_b = 1$) and $Q$ is the charge which is, in conventional Q-ball literature, is interpreted as the particle number. The Q-balls located under the $M = Q$ line in the right panel of Fig. 8 are then stable.

Several families of solutions could in principle be constructed extending the above results. Let us mention three possibilities: (i) radial excitations of the spherically symmetric solution, where the scalar field presents nodes at some values of the radial variable (see e.g. [26, 27]); (ii) further angular excitations corresponding to higher values of the integers $k$ and $m$; (iii) a mix of (i) and (ii).
VII. FINITE $N_c$

The large-$N_c$ limit leads to an effective potential with continuous U(1)-symmetry and consequently to Q-balls. Although a detailed numerical investigation of this case is out the scope of the present paper, it is worth commenting the situation at finite $N_c$.

When $N_c$ is finite (and $\geq 2$), the symmetry of the Lagrangian is a discrete, $Z_{N_c}$ one enforced by the potential term $a_{N_c}\left(\phi^{N_c} + \phi^{*N_c}\right)$, causing the appearance of a term $a_{N_c}N_c\phi^{N_c-1}$ ($a_{N_c}N_c\phi^{*N_c-1}$) in the equation of motion for $\phi$ ($\phi^*$). One readily sees that the ansatz (12) leads to incompatible equations unless $\omega = 0$. In this case, the equations of motion (18) and (21) are recovered. So all the Q-ball solutions with $\omega = 0$ existing at infinite $N_c$ are expected to exist at finite $N_c$ too. In particular, we have found such solutions in the spherically symmetric case, and we have no argument suggesting that axially symmetric solutions with vanishing $\omega$ do not exist, although they are technically complicated to build.

Which quantum numbers could be used to label these finite-$N_c$ solutions? The charge $Q$ labelling Q-balls is a consequence of the U(1) symmetry, so it is no more relevant. However, $Q$ is linked to the total angular momentum $J = kQ$ of the solution, which is defined from the energy-momentum tensor, as well as the mass $M$ of the solution. So $M$ and $J$ are still good observables to classify solutions at finite $N_c$, instead of $M$ and $Q$.

The Q-ball-like configurations that one could find at finite $N_c$ are likely to be unstable because of the absence of a conserved charge $Q$. From the paper [10], we already have evidences that $N_c = 3$ configurations of the form $\phi(x^0, \vec{x}) = a(x^0)$ exist, where $a(x^0)$ start from the “deconfined minimum” of the potential and falls down to the confined one as time increases. This is an example of a solution modelling an unstable configuration of deconfined matter. So we think that unstable solutions of the type $\phi(x^0, \vec{x})$ may exist, such that $\phi(0, \vec{x}) = \chi(\vec{x})$ can be identified with of the aforementioned $\omega = 0$ solutions, but with $\phi(\infty, \vec{x}) = 0$. This kind of solutions could be interpreted as an unstable plasma ball.
VIII. CONCLUSIONS AND OUTLOOK

In this paper, we have used some knowledge of Q-balls developed several years ago in a context of non-topological solitons within an effective model attempting to describe qualitatively the deconfining phase transition in the large-$N_c$ limit. The effective theory used is a scalar field theory with U(1)-symmetric potential (seen as the infinite $N_c$ limit of a $Z_{N_c}$-symmetric theory), where the complex scalar field is the color-averaged Polyakov loop. At the deconfinement temperature, the effective potential has two degenerate minima mimicking the first-order deconfinement phase transition. Such an effective potential has a shape that strongly resembles to potentials typically used in the study of Q-balls, motivating the present study.

For technical convenience, the infinite wall of the effective Polyakov loop potential occurring for large norms of the effective field have been replaced here by a large power of the scalar field. As expected, the main families of Q-balls, obtained in previous studies, can be constructed for this potential too. Through an investigation of the energy density distribution in the different Q-balls obtained, we have been able to interpret some of them as bubbles of deconfined matter, or quark-gluon plasma. The different shapes we have found correspond to (by increasing mass for a given charge): spheres, tori, or two-bell bound states. These last two solutions have been obtained here for the first time within a Polyakov-loop model. The physical masses and sizes of the obtained solutions cover a large range of values; we recall that the lightest Q-ball is a spherically symmetric one with a mass $M \approx 1.6$ GeV and a typical size of 1.5 fm for the deconfined region. Torus- and two-bell like solutions are systematically heavier (and larger) than this solution.

Returning to potential (2), it could be mentioned that our Q-balls corresponding to $\omega = 0$ could provide solutions of the more realistic, finite-$N_c$, $Z_{N_c}$ equation. We believe that our Q-balls with generic values of $\omega$ could produce mean values (or suitable initial profile) of more realistic time-dependent solutions of the potential (2). As far as the stability of the solutions is concerned, the non conservation of $Q$ for the realistic equations would allow the lump to decay, as expected in the context of the fireball expansion in hadronic collisions.

The precise behaviour of the solutions in regions of low $\omega$ were not pushed to details since
it was not the aim of this exploratory study: A more detailed classification of solutions, with higher angular momentum in particular, as well as a more realistic description of the gluon plasma – through the building of unstable, finite-$N_c$, solutions for example– is left for future works.
