Abstract

Objective
To highlight potential epigenetic risk factors for blood pressure (BP) and ischemic stroke (IS) in loci identified by genome-wide association studies (GWASs).

Methods
We detected DNA methylation for BP (317,756 individuals from UK Biobank) and IS (521,612 individuals from MEGASTROKE) in Europeans by using the summary data–based mendelian randomization (SMR) method. We selected the most relevant gene to validate the association in 1,207 patients with hypertensive IS and 1,269 controls from the Chinese populations.

Results
We first identified 173 CpG sites in 90 genes, 337 CpG sites in 142 genes, and 9 CpG sites in 7 genes that were significantly associated with systolic, diastolic BP, and IS, respectively. The methylation level of cg12760995 in CASZ1 was associated with systolic ($P_{SMR} = 1.74 \times 10^{-12}$), diastolic BP ($P_{SMR} = 2.48 \times 10^{-10}$), and IS (odds ratio [OR] = 0.92 [95% confidence interval [CI]: 0.91–0.94]; $P_{SMR} = 2.28 \times 10^{-8}$) in Europeans. The methylation levels of 17 sites in the promoter of CASZ1 were measured in the Chinese individuals, and 10 of them were significantly associated with IS. The higher methylation level of CASZ1 was associated with a lower risk of IS (adjusted OR = 0.97 [95% CI: 0.96–0.99]). CASZ1 seemed to be hypomethylated in hypertensive cases, and the level was negatively correlated with BP. Systolic and diastolic BP mediated approximately 61.2% ($p = 3.49 \times 10^{-6}$) and 45.0% ($p = 0.0029$) of the association between CASZ1 methylation and IS, respectively.

Conclusions
This study identified DNA methylations that were associated with BP and IS. CASZ1 was hypomethylated in Chinese patients with hypertensive IS.
DNA methylation occurs primarily on CpG dinucleotide to control transcription. Studies have shown that blood DNA methylation play important roles in BP regulation. It has been known that epigenetic regulation participates in the development of hypertension through a comprehensive mechanism, which targets different levels of complexity including the renin-angiotensin-aldosterone system, the vascular wall, and specific cell types within the vessels. Some studies have been performed to identify epigenetic risk factors for stroke. DNA methylation has also been identified as potential drug targets in the treatment of atherosclerotic diseases, including stroke. The DNA methylation patterns could be used as potential biomarkers of stroke. Even so, the role DNA methylations play in hypertension and stroke remains poorly known.

The functional factors among the GWAS-identified loci were not fully understood. A major challenge remained in the post-GWAS era was uncovering causal factors underlying the GWAS hits. Here, we presented a 2-step study to identify additional epigenetic risk factors for BP and IS. First, we applied the summary data-based mendelian randomization (SMR) method to integrate data from large-scale GWAS with methylation quantitative trait loci (mQTL) study to detect BP- and IS-associated methylation in the European populations, among which the public available GWAS summary data are very rich. Second, we examined the associations between the identified methylation and BP and IS among individuals from the Chinese populations.

**Methods**

**Mendelian randomization analysis**

Mendelian randomization (MR) is an instrumental variable analysis approach that uses genetic variants as instrumental variables (e.g., mQTLs) to test whether an exposure (e.g., DNA methylation level) has a causal effect on an outcome (e.g., IS). The SMR method can identify potential functionally relevant methylations in the GWAS identified loci by integrating independent GWAS summary statistics with mQTL data. By using public summary data from large-scale GWAS and mQTL meta-analysis studies, the SMR method evaluated the causal associations in very large samples so that the statistical power was increased. In this study, we first conducted SMR analysis to identify DNA methylations that were causally associated with BP and IS, by which we could prioritize functionally relevant genes in the GWAS loci and find the shared genetic influences.

The BP GWAS data set comprised the summary statistics for the association between more than 10 million single nucleotide polymorphisms (SNPs) and systolic BP (SBP) and diastolic BP (DBP) that were evaluated in 317,756 individuals enrolled in the UK Biobank. This data set can be downloaded at ldsc.broadinstitute.org/gwashare/. The IS GWAS, which comprised 521,612 individuals of European ancestry, is the largest GWAS on IS to date. Raw data used in the present analysis were the downloaded summary results from this GWAS, which included summary data of almost 8 million SNPs and indels for IS. These data set was available at the MEGASTROKE website (megastroke.org/). The zip file downloaded contained 10 files for the GWAS results of any stroke, any ischemic stroke, large artery stroke, cardioembolic stroke, and small vessel stroke subtypes from Europeans and trans-ethnicity samples. In this study, we restricted the analysis to the IS subtype in Europeans, only the file “MEGASTROKE2.AIS.EUR.out” inside the zip file was used in the analysis.

The available summary data contained information on the rs number, chromosome, position, effect allele, other allele, sample size, beta, standard error, t statistic, and p value for each SNP. Allele frequencies for the SNPs were obtained from the 1000 Genomes Project (Europeans). The BP and IS GWAS summary data were formatted (the plain file contains 8 columns: rs number, effect allele, other allele, frequency, beta, standard error, p value, and sample size) for the SMR analysis by using the R language.

Another file required for the SMR analysis was the mQTL data file (in binary format). The mQTL summary data were from the study conducted by McRae et al. DNA methylation was measured on 614 individuals from the Brisbane Systems.
Genetics Study and 1,366 individuals from the Lothian Birth Cohorts using Illumina HumanMethylation450 BeadChips. The mQTL summary data in SMR binary format can be downloaded from cnsgenomics.com/software/smr/#Data-Resource. Only the DNA methylation probes (88,712) with at least a cis-mQTL at $p < 5.0 \times 10^{-8}$ and only SNPs within 2 Mb distance from each probe were available.

SMR jointly analyzed the mQTL and BP and IS GWAS summary statistics to test for association between methylations and BP and IS due to the shared variant at a locus. A heterogeneity in dependent instruments (HEIDI) test for heterogeneity in the resulting association statistics was performed. $P_{\text{HEIDI}} > 0.05$ means that there was no significant heterogeneity underlying the mQTL signals (the basic assumption of MR analysis). We ran SMR (version 0.712) with default parameters in a command line program, which was downloaded from cnsgenomics.com/software/smr/. Genotype data of HapMap r23 CEU were used as a reference panel to calculate the linkage disequilibrium (LD) correlation for SMR analysis.

Study sample from Chinese populations
We conducted a case-control study investigating the association between the DNA methylations of the identified genes and IS among Chinese individuals. The IS cases were randomly selected from the China Antihypertensive Trial in Acute Ischemic Stroke (CATIS) project, a clinical trial registered at clinicaltrials.gov (Identifier: NCT01840072). The CATIS trial was a multicenter, single-blind, blinded end point, randomized clinical trial conducted in 26 hospitals across China from August 2009 to May 2014. In brief, 4,071 patients aged 22 years or older who had IS confirmed by CT or MRI of the brain within 48 hours of symptom onset and who had an elevated SBP between 140 mm Hg and less than 220 mm Hg were recruited.

The controls were randomly selected from the Suzhou Metabolic Syndrome Study (SMSS). The SMSS was an observational cohort study of 18,461 individuals in 6 rural townships in of Suzhou in China’s Jiangsu province. Participants who had no evidence of end organ damage, including coronary heart disease, stroke, chronic renal disease, and tumors, and signed informed consent were recruited at baseline. By considering both sequencing cost and statistical power, about 1,200 cases and 1,200 controls were chosen in this study.

Standard protocol approvals, registrations, and patient consents
This study was approved by the institutional review boards or ethical committees at Soochow University. Written consent was obtained from all study participants.

Measurements
Three sitting consecutive BP measurements (30 seconds between each) were taken by trained staff using a standard mercury sphygmomanometer according to a standard protocol, after the participants had been resting for 30 minutes. The first and fifth Korotkoff sounds were recorded as SBP and DBP, respectively. The average of the 3 BP measurements was calculated for each participant and used in the analyses. Hypertension was defined as SBP $\geq$140 mm Hg and/or DBP $\geq$90 mm Hg and/or use of antihypertensive medication in the last 2 weeks. For all the participants, overnight fasting blood samples were obtained, plasma (serum) and white blood cell samples were isolated, and DNA was extracted. The specimens were frozen at $-80^\circ$C until laboratory testing. A modified hexokinase enzymatic method was applied to test fasting blood glucose (FBG) levels. Total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), and triglycerides (TGs) were analyzed enzymatically using a Beckman Synchroon CX5 Delta Clinical System (Beckman Coulter, Inc., Fullerton, California) with commercial reagents. Low-density lipoprotein cholesterol (LDL-C) levels were calculated using the Friedewald equation for participants who had less than 400 mg/dL TG.

DNA methylation sequencing
We applied the targeted bisulfite sequencing to measure DNA methylation levels. Briefly, CpG islands adjacent to the promoter region of the gene were analyzed, and based on these CpG islands, the targets were confirmed (figure e-1, links.lww.com/NXG/A313). Genomic DNA passed quality control (concentration $\geq$20 ng/µL, total DNA $\geq$ 1 µg, OD260/280 = 1.7–2.0, OD260/230 $\geq$ 1.8) was bisulfite converted using the EZ DNA Methylation-Gold Kit (ZYMO, CA), and then, the targeted DNA fragments were amplified by PCR. The amplified products were sequenced on an Illumina MiSeq benchtop sequencer (Illumina, CA). The methylation level of each CpG site was calculated as the percentage of the methylated cytosines over the total tested cytosines. The average methylation level for a target was calculated using methylation levels of all measured CpG sites within the target. To test the reliability of methylation levels for each CpG site, 20 samples were randomly selected for duplicate detection.

Statistical analysis
The differences of baseline risk factors between cases and controls were compared, using a Student $t$ test for continuous variables and $\chi^2$ tests for categorical variables. The methylation levels of each CpG site in IS cases and controls were assessed by 2-tailed unpaired Student $t$ tests; bar plots depict the means, and the error bars in the figures represent SDs. Linear regression models were used to assess the associations between methylation levels and BP. Logistic regression models were used to calculate odds ratios (ORs) and 95% confidence intervals (CIs) for hypertension and IS for per 1-percent increased with methylation levels. The potential covariates such as age, sex, smoking, drinking, body mass index (BMI) SBP, DBP, TC, and FBG were included in the multivariate models. The analyses were performed in the combined sample and subgroups stratified by sex. Causal mediation analysis was performed to examine the mediation effect of BP on the association between methylation and IS. The mediation analysis was conducted by using the R package
Results

BP-associated CpG sites

By integrating data from large-scale BP GWAS with mQTL study from European populations, we found 173 CpG sites in 90 genes that were significantly associated with SBP and 337 CpG sites in 142 genes that were significantly associated with DBP ($P_{SMR} < 5.67 \times 10^{-7}, P_{HEIDI} > 0.05$). The total number of CpG sites (or genes) was 470 (199). Among them, 40 (33) were shared by SBP and DBP. The detailed information about these BP- and DBP-associated CpG sites is presented in tables e-1 and e-2 (links.lww.com/NXG/A313), respectively. Among the identified genes, the top 20 genes that contained the most significant methylation associated with SBP were CNNM2, NTSC2, SLCSA11, FES, TNR6A, CASZ1, TXNB, FAM109A, ADAMTS8, HOXA13, NEIL2, SLC10A4, SYNPO2L, GATA4, BRAP, SH2B3, REL, CEP68, MSRA, and GOSR2 (figure 1). The top 20 genes that contained the most significant methylation associated with DBP were FAM109A, NOV, CPEB4, ZSCAN12L1, ZNF389, CNNM2, ZSCAN16, SH2B3, CYP21A2, FES, C6orf10, MSH5, SDCCAG8, REL, MSRA, HLA-DMA, ULK4, ZNF192, SRRT, and HLA-B (figure 1).

IS-associated CpG sites

By integrating data from large-scale IS GWAS with mQTL study from European populations, we found that more than 6,000 CpG sites were nominally associated with IS ($P_{SMR} < 0.05$). Among them, $p$ values of 28 CpG sites in 12 loci (14 genes) exceed $1 \times 10^{-5}$ (figure 1) and 10 of them could be considered significant ($P_{SMR} < 5.67 \times 10^{-7}$, Bonferroni correction). Nine of these significant sites in CASZ1, SLC25A44, FOXQ1, SH3PXD2A, ACAD10, LRCH1, and SLC44A2 passed the HEIDI test ($P_{HEIDI} > 0.05$) (table 1).

The selected gene CASZ1

Among the 199 identified BP-related genes, we noticed that CASZ1 SNPs were strongly associated with both SBP ($P_{GWAS} = 5.62 \times 10^{-14}$) and DBP ($P_{GWAS} = 2.81 \times 10^{-11}$) and DNA methylation levels ($P_{mQTL} = 1.37 \times 10^{-22}$), and CASZ1 methylation was significantly associated with both SBP ($P_{SMR} = 1.74 \times 10^{-12}$) and DBP ($P_{SMR} = 2.48 \times 10^{-10}$) in Europeans (tables e-1 and e-2, links.lww.com/NXG/A313, figure 2). Among the 7 identified IS-related genes, CASZ1 SNPs were strongly associated with both IS risk ($P_{GWAS} = 5.51 \times 10^{-9}$) and DNA methylation levels ($P_{mQTL} = 1.37 \times 10^{-22}$), and CASZ1 methylation was significantly associated with IS (beta = $-0.08$, OR = $0.92$ [95% CI: 0.91–0.94]; $P_{SMR} = 2.28 \times 10^{-8}$) in Europeans (table 1, figure 2).

CasZ1 gene SNPs have also been reported to be strongly associated with BP, hypertension, and incident hypertension and cardiovascular diseases in the Chinese populations.$^{9,26}$ Until now, the associations between CASZ1 methylation and BP and IS have not yet been clarified. Therefore, based on these evidence, we conducted a case-control study to investigate the association between the DNA methylation in this gene and IS to identify additional risk factors for IS among Chinese individuals.

Association between CASZ1 methylation and BP and IS in Chinese

A total of 1,207 IS cases and 1,269 controls were included for bisulfite sequencing (table e-3, links.lww.com/NXG/A313). The mean age and the proportion of males, smokers, and drinkers were not different between cases and controls. Compared with the controls, mean SBP, DBP, BMI, TC, LDL-C, TG, and FBG levels were all significantly higher, whereas the HDL-C level was lower in IS cases ($p < 0.05$). Among the 1,207 patients with IS, 1,005 (83.3%) were thrombotic strokes, 54 (4.5%) were embolic strokes, and 173 (14.3%) were small-vessel lacunar strokes. Three patients were both thrombotic and embolic, 22 were both thrombotic and lacunar. Thrombotic strokes included both intra- and extracranial atherosclerotic strokes. No cryptogenic stroke was included. Among the 1,269 controls, 381 (30.02%) were patients with hypertension (table e-4, links.lww.com/NXG/A313).

We successfully measured the methylation levels of 17 sites inside a CpG island in CASZ1. According to the duplicate detection in 20 individuals, there was no significant difference between the 2 tests for the methylation levels of each of these 17 sites (paired $t$ test $p > 0.05$). The missing rate of methylation level data was 0.91% (11) for cases and 0.23% (3) for controls. The methylation levels of 10 of these sites were significantly associated with IS in univariate analysis ($p < 3.0 \times 10^{-5}$) (figure e-2, links.lww.com/NXG/A313). The methylation levels of the associated CpG sites were highly correlated (figure e-3, links.lww.com/NXG/A313) and seemed to be hypomethylated in the patients with hypertensive IS (table 2). After adjusted for covariates, the associations between methylation levels of 8 sites and IS were nominally significant, and the associations between methylation levels of CASZ1_1-70 (adjusted OR = 0.99 [0.98–1.00]; $p = 7.26 \times 10^{-4}$) and CASZ1_67 (adjusted OR = 0.98 [0.98–0.99]; $p = 5.54 \times 10^{-5}$) and IS were significant. These sites were associated with IS in male participants but not females (table 2). The mean methylation level of this tested target was significantly lower in the patients with hypertensive IS than the controls (figure 3A). The higher CASZ1 gene methylation level was significantly associated with a lower risk of IS (adjusted OR = 0.97 [95% CI: 0.96–0.99]; $p = 1.59 \times 10^{-4}$), and the association was significant in males (adjusted OR = 0.96 [95% CI: 0.94–0.98]; $p = 4.41 \times 10^{-5}$) (table 2).

The methylation levels of 4 and 3 of the 17 sites were significantly associated with SBP and DBP ($p < 1.0 \times 10^{-5}$) in

Data availability

Data are available to researchers on request for purposes of reproducing the results or replicating the procedure by directly contacting the corresponding author.
univariate analysis (table e-5, links.lww.com/NXG/A313), respectively. After adjustment for IS status and other covariates, the associations of methylation levels of 3 sites with SBP were nominally significant. The mean methylation level of this target seemed to be hypomethylated in hypertensive cases (figure 3B) and was negatively correlated with SBP and DBP (figure 3, C and D, respectively). The association between the mean methylation level of this target and SBP was still nominally significant after adjustment for IS status and other covariates (beta = −0.3641, p = 0.0341). In the median analysis, the

** Minor allele frequency in European populations.

The results were from the MEGASTROKE GWAS.
The 3 panels present the associations between CASZ1 methylation and SBP (A), DBP (B), and IS (C) in European populations. Each panel consists of 2 parts. The x-axis represents the genomic position (GRCh37.p13). The lower part of each panel shows the results of mQTL. The y-axis represents $-\log_{10}(P_{\text{mQTL}})$. In this part, we can see that CASZ1 SNPs were strongly associated with DNA methylation levels (mQTL). The upper part of each panel shows the results of GWAS and SMR analysis. The y-axis represents $-\log_{10}(P_{\text{GWAS or SMR}})$. In this part, we can see that CASZ1 SNPs were strongly associated with SBP (A), DBP (B), and IS (C). According to the mendelian randomization analysis, a DNA methylation level of cg12760995 in the CASZ1 gene was significantly associated with SBP (A), DBP (B), and IS (C). DBP = diastolic BP; SBP = systolic BP; GWAS = genome-wide association study; IS = ischemic stroke; SMR = summary data-based mendelian randomization.

Abbreviations: CATIS = China Antihypertensive Trial in Acute Ischemic Stroke; CI = confidence interval; FBG = fasting blood glucose; OR = odds ratio; SBP = systolic BP; TC = total cholesterol.

* The numbers in the names represented the position of the site in the genomic fragment sequenced.

GRCh37.p13.

Adjusted for age, sex, smoking, drinking, BMI, SBP, TC, and FBG.
mediation effect estimations were $-0.0445 \ (p = 0.0021)$ and $-0.0315 \ (p = 0.0062)$ for SBP and DBP, respectively. SBP and DBP mediated approximately 61.2\% \ (p = 3.49\times10^{-6}) and 45.0\% \ (p = 0.0029) of the association between CASZ1 methylation and IS, respectively (figure 4).

**Discussion**

The current study represented an effort to identify potential causal epigenetic factors for BP and IS by integrating data from large-scale GWASs initiative on DNA methylation, BP, and IS risk. Hundreds of CpG sites in important genes (e.g., CASZ1) were found to be causally associated with BP and IS in Europeans by using this strategy. In addition, by applying a target sequencing method, we found that CASZ1 methylations were associated with BP and IS in the Chinese populations.

DNA methylation plays an important role in BP regulation and IS pathology and could be potential therapeutic targets.\(^{15-17}\) Previous studies have identified some DNA methylations for hypertension and IS\(^{10,12-14}\), however, the statistical power of these traditional case-control studies was very limited due to the small sample size, and reverse causation always existed in observational studies. Integration of GWAS data with data from the mQTL study by applying the SMR approach was a possible way to identify relevant methylations in the GWAS loci.\(^{19}\) This methodology not only limited bias due to confounding and was not

---

**Figure 3** The relationship of mean CASZ1 methylation levels with BP and IS among Chinese

The mean methylation levels for CASZ1 for each individual were calculated using methylation levels of all measured CpG sites within the genomic fragment sequenced. The bar plots depict the means, and the error bars in the figures represent SDs; the differences were assessed by t tests. (A) This gene was significantly hypomethylated in the 1,207 patients with hypertensive IS compared with the 1,269 controls. (B) This target was hypomethylated in the hypertensive cases (1,207 IS hypertensives plus 381 non-IS hypertensives or only 381 non-IS hypertensives) compared with the 888 controls. The 2 scatter plots present the relationship between the mean methylation level of CASZ1 and SBP (C) and DBP (D). The blue lines represent linear regression lines, and the gray areas represent the corresponding 95% confidence intervals. DBP = diastolic BP; IS = ischemic stroke; SBP = systolic BP.
CASZ1 encodes a zinc finger transcription factor. CASZ1 is required to directly regulate an EGFL7/RhoA-mediated pathway to promote vertebrate vascular development and plays a key role in cardiac homeostasis and dilated cardiomyopathy. The association between CASZ1 methylation and IS has not been reported. The newly identified methylation loci, which have implicated the importance of these genes in BP regulation and IS etiology. Our study highlighted the involvement of methylation in these loci. The mQTLs were detected in blood samples, so our study identified blood cell DNA methylations that were associated with BP and IS.

We observed sex differences in the association between CASZ1 methylation and IS risk in this study. Significant differences between males and females were observed for age, smoking, and drinking in our data. The CASZ1–BP association has suggested to be influenced by age in a sex-specific manner, which documented the modulation of genetic effects on BP by sex and age. Besides, sex- and age-specific associations between methylation and diseases for other genes and diseases have been reported. Blood cell DNA methylation can be influenced by smoking and drinking. However, in our study, no significant association between sex and methylation was observed in patients with IS or the controls or combined samples. Methylation levels were not associated with age, smoking, or drinking either. No significant interaction effect between methylations and age, smoking, or drinking on IS was found. The associations between methylation levels and IS risk were not significant in subgroups stratified by smoking or drinking. The differences of age, smoking, and drinking between the men and the women in this study might not account for the observation of sex difference. The sex differences in the association between CASZ1 methylation and IS risk needed to be clarified in future studies.

In addition to CASZ1, methylations of other genes identified in the MEGASTROKE GWAS were found to be potential causal factors for IS in this study. The original GWAS has linked the genetic variants of these genes to IS risk, whereas the present study associated their methylations with IS. The identified genes have been shown to play certain roles in the cardiovascular system. For example, the SLC25A44 gene, encodes solute carrier family 25 member 44 that is widely expressed in the CNS, has been identified to be associated with intracerebral hemorrhage. SLC44A2 (solute carrier family 44 member 2), also named CTL2 (choline transporter-like protein 2), codes for a human leukocyte alloantigen. It has been shown that SLC44A2 is expressed on the endothelium, where it expresses an isoform involved in choline transport. This gene was a well-known susceptibility gene for thrombosis. SLC44A2 may be involved in choline uptake in mitochondria, which is the rate-limiting step in DNA methylation. Methylation in this gene has been shown to be associated with MS but not stroke.
In summary, the present study found out DNA methylations were newly identified to be hypomethylated in Chinese patients with hypertensive IS. This study identified new risk factors, and the findings may increase our understanding on the role of DNA methylations in the pathogenesis of IS. Although we have detected significant associations, cell experiments and animal studies are suggested to carry out to confirm the causality and elucidate the mechanism.
