(April 20, 2019)

A crucial assumption in the conventional description of thermal conduction is the existence of local thermal equilibrium. We test this assumption in two simple models of heat conduction. Our first model is a linear chain of planar spins with nearest neighbour couplings, and the second model is that of a Lorentz gas. We look at the steady state of the system when the two ends are connected to heat baths at temperatures $T_1$ and $T_2$. If $T_1 = T_2$, the system reaches thermal equilibrium. If $T_1 \neq T_2$, there is a heat current through the system, but there is no local thermal equilibrium. This is true even in the limit of large system size, when the heat current goes to zero. We argue that this is due to the existence of an infinity of local conservation laws in their dynamics.

It is obvious that existence of extra conservation laws in an isolated classical mechanical system implies breakdown of ergodicity, and hence failure to reach thermodynamical equilibrium. Our results are nontrivial in that we show that this occurs even in the presence of coupling to heat baths which leads to breakdown of the conservation laws at the boundaries of the system. Also, the role of conservation laws in stochastically evolving system is somewhat different from that in deterministic evolution \[3\], and not so well-studied.

Several microscopic models of heat conduction have been studied in the past. The simple model of a harmonic lattice, evolving with classical mechanical equations of motion, and coupled to two heat baths at different temperatures $T_1$ and $T_2$ at opposite ends of the lattice, is known to show anomalous conduction \[4\]. It is found that the heat current $J$ across the sample remains finite as the size of the system $L$ goes to infinity, for a fixed $T_1$ and $T_2$. Simulations of harmonic chains with disorder show that $J$ decreases to zero for large $L$, but only as $L^{-1/2}$ \[5\]. Several models with nonlinear couplings have been studied numerically: the FPU chain with quartic potential \[6\], the Toda lattice \[7\], the so-called ding-a-ling model \[8\], the Frenkel-Kontorova model \[9\] etc. Most of these models are one-dimensional, and all do not show the expected $J \sim (T_1 - T_2)/L$ behavior. The uniqueness of the steady state has been proved only for some special models of heat baths, and only if the temperature difference is sufficiently small \[10\]. In this respect models with stochastic dynamics have been more successful. These typically work with local energy-conserving moves, and often involve introduction of additional degrees of freedom. Creutz has used an algorithm with Maxwell demons to simulate heat conduction in the Ising model \[11\]. Lebowitz and Spohn studied heat conduction in the Lorentz model, and showed that in the Boltzmann-Grad limit of large number of scatterers of very small size, one recovers the Fourier law ($J \sim (T_1 - T_2)/L$) \[12\].
We start with a precise definition of our first model. We consider a linear chain of $L$ planar spins. The spin at site $i$ ($1 \leq i \leq L$) of the lattice is specified by the angle $\theta_i$, $0 \leq \theta \leq 2\pi$. The spins interact with nearest neighbors by ferromagnetic coupling $K$. The Hamiltonian of the system is given by

$$H = -K \sum_{<i,j>} \cos(\theta_i - \theta_j)$$

(1)

where the sum is over all nearest neighbors.

The dynamics is the following: Suppose the instantaneous local field at a site $i$ due to coupling of the neighbors is in the direction $\phi_i$, and the spin at the site is $\theta_i = \phi_i + \delta\theta_i$. Then the transition $\delta\theta_i \rightarrow -\delta\theta_i$ does not change the energy of the system. We assume that such spin flips occur at all sites stochastically with a constant rate (which may be chosen to be $1$). The boundary spins $i = 1, L$ are connected to heat baths. For these spins, the flip rates are the following: A boundary spin $\theta_i$ can change to any value $\theta'_{\alpha}$ with a rate $\alpha$ if the energy change $\Delta E \leq 0$, and with a rate $\alpha e^{-\Delta E/T}$, if $\Delta E > 0$; where $T$ is the temperature of the heat bath.

Note that in this model energy is conserved exactly away from the boundaries of the lattice. In the absence of any coupling to heat baths, this dynamics has been studied by one of us earlier [13]. It was found that, of any coupling to heat baths, this dynamics has been away from the boundaries of the lattice. In the absence of any coupling to heat baths, this dynamics has been away from the boundaries of the lattice. In the absence is the temperature of the heat bath.

Next consider any spin, $\theta_i$, can exchange energy with the bath, keeping other spins unchanged, except for $\theta_1$ which changes by an amount proportional to $\delta\theta_0$.

We use a similar argument to change a neighbour of $\theta_1$, and so on. Thus, there exists an allowed sequence of spin flips by which we can rotate any single spin by an infinitesimal amount. By making many such rotations we can reach any spin configuration. This completes the proof of ergodicity. Note that the proof is valid in all dimensions $d$ and also if more than one spin is in contact with the same heat bath (same $T$).

In one dimension the equilibrium properties of the $XY$ model are easily determined. We define $\Delta\theta_i = \theta_{i+1} - \theta_i$. Then clearly the $\Delta\theta_i$ are independent random variables. For a mesoscopic description, we define coarse-grained densities by averaging the corresponding microscopic quantity over length scales $\ell$, with $1 < \ell < L$. Let $u^{(n)}(x)$ be the coarse-grained density corresponding to $\cos^n(\Delta\theta_i)$ for $i$ lying in a neighborhood of the point $x$. In equilibrium, at inverse temperature $\beta$, there is no dependence on $x$, and one gets

$$u^{(n)}_i = \frac{\int \cos^n(\Delta\theta) e^{\beta K \cos(\Delta\theta)} d(\Delta\theta)}{\int e^{\beta K \cos(\Delta\theta)} d(\Delta\theta)}$$

(2)

Eliminating $\beta K$ from these equations we can express $u^{(n)}$, for $n \geq 2$, as explicit nonlinear functions of $u^{(1)}$, i.e. $u^{(n)} = F^{(n)}(u^{(1)})$.

We consider now the case when the two ends are connected to different heat baths, at temperatures $T_1$ and $T_2$. We show that, in the NSS, LTE is not achieved.

In this dynamics, whenever a spin flip occurs, the values of $\Delta\theta$ on the two adjacent bonds get interchanged. This means that the densities $u^{(n)}$ are locally conserved for all positive integers $n$. For each of these quantities one can write a corresponding current. The current from the $(x - 1)$th bond to the $x$th bond is given by

$$J^{(n)}(x) = (- < \cos^n(\Delta\theta_{x-1}) > + < \cos^n(\Delta\theta_x) >)$$

$$= -\nabla u^{(n)}(x)$$

(3)

In the steady state, in one dimension, $J^{(n)}(x)$ must be independent of $x$, and hence $u^{(n)}$ vary linearly across the chain for all $n$. Their value at the two ends are determined by the temperatures at the ends. Then, eliminating the coordinate $x$, $u^{(n)}(x)$ is expressible as a linear function of $u^{(1)}(x)$, for all $n$. But, as shown above, in equilibrium, $u^{(n)}$, for $n \geq 2$ are nonlinear functions of $u^{(1)}$. Thus, we have constructed a simple model in which the current is conserved locally proportional to the gradient of energy density, but there is no LTE (Fig. 1). This result is true even in the limit of system size $L \rightarrow \infty$, when the heat current through the lattice becomes infinitesimal.

For a simple extension of the above result, consider a linear chain in which there is one bond with a different bond-strength $K'$. Then the quantities $u^{(n)}$ ($n \geq 2$) are not conserved at this ‘bad’ bond. In this case, the currents take different values $J^{(n)}_1$ and $J^{(n)}_2$ to the left and right of the bond respectively (for $n \geq 2$). In this case, there are no strict conservation laws, but $u^{(n)}$ are still linear functions of $u^{(1)}$ in each (left or right) half of the chain, and LTE is still not obtained. This conclusion has also been checked in simulations (Fig. 2).

In higher dimensions, there are no known locally conserved quantities, other than energy, in the spin model. Hence, we expect LTE to be attained. Indeed, a numerical simulation of a $40 \times 40$ lattice with $T_1 = 1.4K$, and $T_2 = 0.4K$ agrees fully with this conclusion. In this case, we checked that the observed value of $< u^{(2)}(x) >$ at any point $x$ in the NSS agrees very well with the value of $u^{(2)}$.
in the *homogeneous equilibrium state* having energy density $u^{(1)}(x)$. Similarly, if we consider a dimerized chain with alternating coupling constants $K$ and $K'$, then there are no conserved quantities other than the energy density. In this case, the results of our simulations (also shown in Fig. 1) confirm that the NSS does show LTE even in one dimension if $K \neq K'$.

Our second example of absence of LTE in heat conduction is provided by the model of the $d$-dimensional Lorentz gas studied earlier by Lebowitz and Spohn [12]. The model describes a gas of non-interacting point particles moving in a box, undergoing elastic scattering by a random assembly of fixed obstacles of arbitrary shape (Fig. 3). In this model, all collisions with the obstacles are elastic, and energy is conserved. But collisions between the particles and the two walls (at $x = 0$ and $x = L$) are inelastic, and lead to the energy after collision being thermalized corresponding to the temperature of the wall.

Let $\rho(E, x)dE$ be the average density of particles having energy between $E$ and $E + dE$ in a small volume centered at point $x$. Then all moments $\mu^{(n)}(x) = \int E^n \rho(E, x)dE$ of this distribution function are locally conserved.

Now consider the effect of coupling it to two different reservoirs at temperatures $T_1$ and $T_2$. Let $p(x)$ be the probability that a randomly chosen particle in the small volume chosen near $x$ was introduced at the left end. Then as collisions with scatterers do not change the energies, clearly $\rho(E, x)$ is given by

$$\rho(E, x) = p(x)\rho(E, x = 0) + (1 - p(x))\rho(E, x = L) \quad (4)$$

The $x$-dependence of $\rho(E, x)$ comes only from the spatial dependence of $p(x)$. As the linear combination of two maxwellians is not a maxwellian, and the distribution must be a maxwellian in thermal equilibrium, it follows that there is no thermal equilibrium in the Lorentz model [4]. Also we expect the heat flow to be diffusive ($J \sim 1/L$) in the limit $L \gg \ell$, where $\ell$ is the mean free path of the Lorentz particles. Note that an equation similar to Eq. (4) can be written down for the first model also.

If we allow inelastic scattering with local energy conservation (each scatterer can store a small amount of energy, which can be exchanged with the scattered particles), the infinity of conservation laws goes away, and we expect that then the model would show LTE, and normal conduction.

To summarize, in this Letter, we studied two simple models of heat conduction, and showed that local thermal equilibrium is not reached as both the models have an infinity of locally conserved quantities. These counterexamples should help understand better the mechanism of local thermal equilibration in nonequilibrium systems, in general.

We thank Mohit Randeria and Jean-Pierre Eckmann for critically reading the manuscript, and one of the referees for several useful comments on an earlier version of this paper.
