ABSTRACT
Cluster star-forming galaxies are found to have an excess of Far-Infrared emission relative to Hα, when compared to those in the field, which could be caused by intense AGN activity, dust and/or declining star formation histories. Here we present spectroscopic observations of Hα emitters in the Cl 0939+4713 (Abell 851) super-cluster at z = 0.41, using AF2+ WYFFOS on the WHT. We measure [Oii], Hβ, [Oiii], Hα and [Nii] for a sample of 119 Hα emitters in and around the cluster. We find that 17 ± 5% of the Hα emitters are AGN, irrespective of environment. For star-forming galaxies, we obtain Balmer decrements, metallicities and ionisation parameters with different methods, individually and by stacking. We find a strong mass-metallicity relation at all environments, with no significant dependence on environment. The ionisation parameter declines with increasing stellar mass for low-mass galaxies. Hα emitters residing in intermediate environments show the highest ionisation parameters (along with high [Oiii]/Hα and [Nii] for a sample of 119 Hα emitters in and around the cluster. We find that 17 ± 5% of the Hα emitters are AGN, irrespective of environment. For star-forming galaxies, we obtain Balmer decrements, metallicities and ionisation parameters with different methods, individually and by stacking. We find a strong mass-metallicity relation at all environments, with no significant dependence on environment. The ionisation parameter declines with increasing stellar mass for low-mass galaxies. Hα emitters residing in intermediate environments show the highest ionisation parameters (along with high [Oii]/Hα and high [Oiii]/[Oii] line ratios, typically twice as large as in the highest and lowest densities), which decline with increasing environmental density. Dust extinction (A_Hα) correlates strongly with stellar mass, but also with environmental density. Star-forming galaxies in the densest environments are found to be significantly duster (A_Hα ≈ 1.5 – 1.6) than those residing in the lowest density environments (A_Hα ≈ 0.6), deviating significantly from what would be predicted given their stellar masses.

1 INTRODUCTION
The last decades have seen a tremendous observational, modelling and theoretical effort towards understanding galaxy formation and evolution in various environments. One of the key observables that has now been widely measured is the star formation rate density (ρ_SFR), which many studies have shown to rise out to z ∼ 2 (e.g. Lilly et al. 1996; Karim et al. 2011; Burgarella et al. 2013; Sobral et al. 2013a). Measuring ρ_SFR as a function of redshift (z), but also understanding its variation with environment and with internal processes is key to our understanding and to test state-of-the-art models (e.g. Illustris, EAGLE; Vogelsberger et al. 2014; Genel et al. 2014; Schaye et al. 2015; Crain et al. 2015).

In the local Universe, star formation depends strongly on environment. Clusters are primarily populated by passive galaxies, while star-forming galaxies are mainly found...
in lower-density environments (e.g. Dressler 1980). It is also well-established (e.g. Best 2004) that the fraction of star-forming galaxies decreases with increasing local galaxy density (often projected local density, Σ) both in the local Universe and at low (z < 0.5) redshift (e.g. Kodama et al. 2004). Stellar mass and/or internal processes connected with the stellar mass assembly also play a key role. While mass and environmental density correlate, it is now possible to disentangle their roles in the local Universe and at higher redshift and to show that both are relevant for quenching star-formation (e.g. Peng et al. 2010; Darvish et al. 2016).

Several studies in a broad range of redshifts have shown that, on average, many properties of star-forming galaxies that are directly or indirectly linked to star formation activity (e.g. star formation rates, specific star formation rates, emission line equivalent widths, main-sequence of star-forming galaxies) seem to be invariant to their environment (e.g. Peng et al. 2010; Wijesinghe et al. 2012; Muzzin et al. 2012; Koyama et al. 2013, 2014; Hayashi et al. 2014; Darvish et al. 2014, 2015b, 2016). Therefore, the main role of the environment seems to be to set the fraction of quiescent/star-forming galaxies (e.g. Peng et al. 2010; Sobral et al. 2011; Muzzin et al. 2012; Darvish et al. 2014, 2016). Nevertheless, recent studies are finding that not all characteristics of star-forming galaxies are independent of environment. For example, metallicities and electron densities have been shown to be a function of environment (e.g. Kulas et al. 2013; Shimasawa et al. 2015), with studies finding that star-forming galaxies have much lower electron densities and slightly higher metallicities in high density environments when compared to lower density/more typical environments (Sobral et al. 2015; Darvish et al. 2015b).

Finding the exact mechanisms of galaxy quenching and their physical agents is still one of the unsolved problems in galaxy evolution. Many internal (e.g. stellar and AGN feedback) and external (e.g. galaxy environment) physical drivers are thought to be linked to the quenching process. Several environmental processes that are able to quench galaxies have been proposed. These include ram pressure stripping (e.g. Gunn & Gott 1972), strangulation (e.g. Larson et al. 1980; Balogh et al. 2000), galaxy–galaxy interactions and harassment (e.g. Mihos & Hernquist 1996; Moore et al. 1998), tidal interaction between the potential well of the environment and the galaxy (e.g. Merritt 1984; Fujita 1998), or halo quenching (e.g. Birnboim & Dekel 2003; Dekel & Birnboim 2006); see Boselli & Gavazzi (2006) for a review. The strength and quenching timescale of each physical process varies depending on many parameters such as the properties of the quenching environment (e.g. density, temperature, velocity dispersion, dynamical state) and those of the galaxy being quenched (e.g. mass, satellite vs. central). However, the ultimate consequence of each effect is to quickly or gradually remove the gas content/gas reservoir of galaxies or heat up the cold gas so that no further star formation activity is possible.

There is substantial evidence for the truncation of the atomic and molecular gas content of cluster galaxies (especially in the outer parts of the disks), possibly due to ram pressure stripping (e.g. Cayatte et al. 1990; Boselli et al. 2008; Fumagalli et al. 2009; see also Boselli & Gavazzi 2014 for a review). In principle, the dust distribution within galaxies should also depend on their host environment, most likely truncated outside-in as galaxies fall into the deeper potential wells of denser clusters. Cortese et al. (2010) showed that atomic-gas-deficient spiral galaxies in the Virgo cluster also demonstrate signs of deficiency in their dust content. Similarly, Cortese et al. (2012) found that the total dust content of atomic-gas-deficient spiral galaxies in Virgo is lower compared to normal field galaxies.

One might naively expect a continuous decline in the star formation and dust content of galaxies from the field to the dense cores of clusters. However, before galaxies undergo a full quenching process in dense regions, they may experience a temporary enhancement in star formation activity, which may complicate how observations are interpreted. For example, ram pressure stripping can initially compress the gas/dust which is favourable for star formation, and thus increasing the column density of the gas and dust (e.g. Gallazzi et al. 2009; Bekki 2009; Owers et al. 2012; Rodiger et al. 2014). Tidal galaxy-galaxy interactions can lead to the compression and inflow of the gas in the periphery of galaxies into the central part, feeding and rejuvenating the nuclear activity which results in a temporary enhancement in star formation activity (e.g. Mihos & Hernquist 1996; Kewley et al. 2006; Ellison et al. 2008). Galaxy–galaxy encounters are more likely to happen when the interacting systems do not have extreme velocities (low-velocity-dispersion environment) and are closer to each other (denser regions). Intermediate-density environments such as galaxy groups, in-falling regions of clusters, cluster outskirts, merging clusters and galaxy filaments provide the ideal conditions for such interactions (e.g. Moss 2006; Perez et al. 2009; Tonnesen & Cen 2012; Stroe et al. 2014, 2015). Therefore, one might expect a temporary enhancement in star formation activity and dusty star formation in intermediate-density environments before the galaxies quench. This has been found in several studies, referring to the intermediate-density environments as sites of enhanced star formation rate, star-forming fraction and obscured star formation activity (e.g. Smail et al. 1999; Best 2004; Koyama et al. 2008; Gallazzi et al. 2009; Koyama et al. 2010; Sobral et al. 2011; Coppin et al. 2012). In practice, filaments may well be the actual dominant intermediate-density environment (e.g. Darvish et al. 2014, 2015b).

The majority of studies rely on the far-infrared (FIR) or ultra-violet radiation (UV), radio/UV or FIR/Hα ratio as an indicator of dust content of galaxies. Koyama et al. (2011) performed an Hα survey of the rich cluster Cl0939+4713 (z = 0.41), and found a strong concentration of optically red star-forming galaxies in the group-scale environment around the cluster. They argue that the excess of the red star-forming galaxies suggests an enhancement of dust-obscured star formation in the group environment. By surveying the same cluster at z = 0.4 with Spitzer (24 µm), Koyama et al. (2013) found that the 24 µm to Hα ratio increases from low to high density. This could be easily interpreted as an increase in dusty star-forming galaxies from low to high densities (in line with e.g. Rawle et al. 2012). However, such high 24 µm to Hα ratios could also mean a higher fraction of AGN activity and/or declining star formation histories. This is because the FIR will measure SFRs over timescales of ~100 Myr, while Hα is much more instantaneous (~10 Myr). Measuring the Balmer decrement
(\(\text{H} \alpha/\text{H}/\beta\)) for star-forming galaxies only (after rejecting any potential AGN) would allow for significant progress.

In this paper, we present a spectroscopic follow-up of the \(\text{H} \alpha\) candidate emitters in Cl\0139+4713 found with Subaru and Suprime cam (S-Cam) and use data from Kobayashi et al. (2013) to study their properties as a function of environment and internal properties. Section 2 discusses the sample and its main properties. Section 3 presents the observations with WHT/AF2, data reduction and emission line measurements. In Section 4 we show and discuss the results: the properties of individual galaxies, the stacked properties and the discussion of the results. Finally, Section 5 presents the conclusions. We use AB magnitudes, a Chabrier (Chabrier 2003) initial mass function (IMF) and assume a cosmology with \(H_0=70\text{km s}^{-1}\text{Mpc}^{-1}\), \(\Omega_M=0.3\) and \(\Omega_\Lambda=0.7\).

2 SAMPLE AND PROPERTIES

2.1 The cluster

The Cl\0139+4713 cluster at \(z = 0.41\) (Abell 851) is one of the best-studied clusters at intermediate redshifts, and several studies have focused on the cluster central region(s) (e.g. Dressler & Gunn 1992; Dressler et al. 1994; Stanford et al. 1995; Smail et al. 1999; Sato & Martin 2006; Dressler et al. 2009; Oemler et al. 2009). Furthermore, wide-field (\(~30' \times 30'\)) optical broad-band and narrow-band imaging surveys of this cluster have also been conducted (e.g. Kodama et al. 2001; Kobayashi et al. 2011) using S-Cam (Miyazaki et al. 2002) on the Subaru Telescope (Iye et al. 2004). Wide-field observations revealed 10 Mpc-scale filamentary large-scale structures around the cluster based on the photometric redshift (photo-z) technique. Such structures around a massive cluster are similar to those found in other super-structures at \(z \sim 0.5 - 0.8\) (e.g. Sobral et al. 2011; Darvish et al. 2014, 2015).

2.2 Narrow-band survey and the sample of \(\text{H} \alpha\) candidates

Kobayashi et al. (2011) conducted an \(\text{H} \alpha\) narrow-band search around Abell 851. The authors used the NB921 filter (\(\lambda_0 = 9196\,\text{Å}, \Delta \lambda = 132\,\text{Å}\)) on S-Cam and were able to identify 445 \(\text{H} \alpha\) emitting galaxies in and around the cluster (see Figure 1) down to a rest-frame equivalent width \((\text{EW})\text{, EW}[\text{H} \alpha + [\text{N}ii]]\) of \(\sim 20\,\text{Å}\) and a star formation rate (SFR) of \(\sim 0.3\,\text{M}_\odot\text{yr}^{-1}\). \(\text{H} \alpha\) emitters are distinguished from other redshift emitters (e.g. Sobral et al. 2013a; Matthee et al. 2015) using colour-colour selections (see Kobayashi et al. 2011, for full details). In this paper, we follow-up 214 sources, a significant fraction (\(~50\%) see Figure 1) of the 445 \(\text{H} \alpha\) emitter candidates found by Kobayashi et al. (2011).

2.3 Multiband photometry and stellar masses

We use multi-band catalogues derived by Kobayashi et al. (2013) to obtain information on the entire \(\text{H} \alpha\) emitters: \(z'\)-band magnitude, \(B - I\), \(B - z'\), \(\text{H} \alpha\) flux and luminosity from NB921, and EW(\(\text{H} \alpha + [\text{N}ii]\)). By using \(B - I\) and \(z'\)-band magnitude, Kobayashi et al. (2013) derive stellar masses (which essentially uses \(z'\) magnitudes and a colour). We follow the same methodology and derive masses by using:

\[
\log(M_*/10^{11}\,\text{M}_\odot) = -0.4(z' - 20.07) + \Delta \log M,
\]

where \(\Delta \log M\):

\[
\Delta \log M = 0.054 - 3.81 \times \exp[-1.28 \times (B - z')] - 0.2.
\]

We note that the final term (\(~0.2\) is added to the equation when compared to e.g. Kobayashi et al. (2013) to convert from a Salpeter IMF to a Chabrier IMF, which we use. The typical (average) stellar mass of the full parent sample is \(10^{9.3^{+0.6}_{-0.5}}\,\text{M}_\odot\). For comparison, \(M^\star\) for star-forming galaxies at \(z = 0.4\) is \(10^{10.9^{+0.3}_{-0.1}}\,\text{M}_\odot\) (Muzzin et al. 2013; Sobral et al. 2014). The reader is also referred to Kobayashi et al. (2013) that shows that \(\text{H} \alpha\) emitters in and around Abell 851 follow the same stellar mass-star formation rate relation as those in the general field (Sobral et al. 2013a, 2014).

We also use local environmental densities as derived in Kobayashi et al. (2013), along with cluster centric distances. We refer the reader to Kobayashi et al. (2013) for more details on how the local environment densities were computed. Local environmental densities vary from \(\log_{10}(\Sigma) \sim 1.3\) to \(\log_{10}(\Sigma) \sim 2.7\). Briefly, local densities, \(\log_{10}(\Sigma)\), are calculated using all cluster member galaxies (photometric redshift selected and those which are \(\text{H} \alpha\) selected) with the nearest-neighbour approach, calculated within a radius to the 10th-nearest neighbour from each source (e.g. Kobayashi et al. 2011; Sobral et al. 2011). This method is in very good agreement with more robust density estimators such as adaptive
smoothing and Voronoi tessellation (Darvish et al. 2015a) and we use it throughout this work.

3 SPECTROSCOPIC OBSERVATIONS

3.1 Observations: AF2 spectroscopy with WHT

AutoFi2 (AF2; Goodsell et al. 2003) + Wide Field Fibre Optical Spectrograph (WYFFOS; Domínguez Palmero et al. 2014) is a multi-object, wide-field, fibre spectrograph mounted at the Prime focus of the 4.2 m William Herschel Telescope (WHT). The AF2+WYFFOS (AF2 for short, from now on) instrument on WHT is made of 150 science fibres, each with a diameter of 1.6′′, which can be allocated to sources within a ∼30×30 arcmin² field of view, although with strong spatial constraints/limitations. We used the Red+4 detector and the R316R grism with a central wavelength of ∼8000 Å. The central wavelength varies slightly depending on the fibre and field location, but for a source at z = 0.4 all our spectra cover the main emission lines we are interested in: [OIII] 3727 Å, Hβ, [OII] 4959, 5007 Å, Hα and [NII] 6584 Å. The R316R has a dispersion of 1.7 Å pix⁻¹ and a resolution of 8 Å, which corresponds to a resolution of just ∼6 Å at z = 0.4.

We followed up 214 candidate Hα line emitters from Koyama et al. (2011) using AF2 on the WHT in La Palma (program ID: W14BN020) on the second half of four nights during 2015 January 22–25 (see Table 1). Targets have estimated emission line fluxes at λ ∼ 9196 Å of 5 × 10⁻¹⁵ erg s⁻¹ cm⁻² to 9 × 10⁻¹⁵ erg s⁻¹ cm⁻² and estimated (rest-frame) EW (Hα+[NII]) in the range 20 Å to 700 Å. We targeted the cluster with 4 different configurations (P1–P4), all centred on the cluster, but with slightly different rotator angles and small offsets, in order to sample as best as possible the highest density regions, but also the regions at larger cluster centric distances. P1 targeted 56 Hα candidates, P2 55, P3 52, and P4 targeted 51 Hα candidates at z ∼ 0.4. In each configuration, fibres which were not possible to allocate to targets due to over-crowding were allocated to sky on the edges of the field of view.

The seeing was 1.0–1.5′′ in the first two nights (for 2 of the configurations), being slightly worse (∼1.5–2′′) for the third night (third configuration), and becoming even worse (2–3′′) for the final night (final configuration). Thus, the success rate for configurations P1 and P2 was higher than for P3 and much higher than P4 (see e.g. Table 1). The sky was clear for the entire observing run. We observed each configuration with individual exposure times of 900s or 450s, observing an offset sky position for the same exposure time for roughly every two science frames (AAB). In total, we obtained ∼13 ks of science exposure time and ∼4 ks of sky exposures per configuration. See Table 1 for more details on the observations.

3.2 AF2 data reduction

In order to reduce the data, we followed the steps as described in Sobral et al. (2015). We took biases and lamp flats both before and after the observations. Arcs were taken using neon, helium and mercury lamps with the fibres in the on-sky configuration; the same procedure was followed for flats. The traces of the fibres on the CCD were curved in the dispersion direction (y axis on the CCD) and the lamp flats were used to correct for this distortion. We fit each (flat) fibre shape with a Y pixel coordinate polynomial as a function of X coordinate. We correct all of the CCD pixels with the polynomial obtained for the closest fibre. We note that these corrections are applied to each configuration (P1–P4) separately. We also apply the corrections to the biases, flats, lamp arcs and the science data.

The final 2D bias subtracted and curvature corrected frames were then sky subtracted using the sky position exposure(s). In order to improve the sky subtraction we also used sky-dedicated fibres to scale the counts. Roughly 20 of such fibres were allocated to sky in each of the 4 pointings/configurations, allowing a robust scaling of the sky. We further obtained the best scaling factor by minimising the residuals after sky subtraction. After subtracting the sky, we extracted sources along the dispersion axis, summing up the counts. We extracted the signal on the flats, normalised the fibre response and flat fielded each spectrum in 1D. We obtained a first order wavelength calibration by using the arcs and obtain a final wavelength calibration per fibre by using the wealth of sky lines (∼100 different lines, from λ ∼ 5570 Å to λ ∼ 10000 Å) on that particular fibre. We do this by extracting the co-added sky frames, and extract each spectrum in the same way as the science spectra. After matching all the sky lines for each fibre/spectrum individually, we obtain a wavelength calibration with an error (rms) of ∼2 Å (rest-frame ∼1.4 Å at z ∼ 0.4), of the order of the pixel scale of ∼2 Å pix⁻¹.

We further investigate the response curve to derive any corrections needed to robustly compare e.g. emission lines being detected at large separations in observed wavelength. We do this by both using stars with a flat spectrum, and also by constructing a flat spectrum by stacking the observed spectra without redshifting them and after masking all emission and absorption lines from the sources themselves. For a flat spectrum, we find a much higher response at the lowest wavelengths, making all sources look very blue. We derive corrections per pointing and apply them to each individual spectrum, by dividing the spectrum by our correction. We then check (for sources with sufficiently high signal to noise continuum) that our spectra yields colours consistent with the broad-band colours. We note that this correction also corrects for the telluric B-band absorption at ∼6860–6890 Å (although this would only affect ∼10% of our sources, those with z > 0.41).

3.3 Redshifts

We were able to observe 214 out of our full sample of 445 potential Hα emitters spread over an area which is very well matched to the AF2 field-of-view (see Figure 1). The R316R grating enabled the de-blending of the Hα and [NII] emission lines at the redshift of the cluster (z = 0.41; separation of ∼20 Å with ∼6 Å resolution). Our spectra have a wide enough wavelength coverage to allow us to search for all main emission lines we need to unveil the nature of the emitters ([NII], Hα, [OII], Hβ and [OIII]).

In order to obtain redshifts for the observed sources (Figure 2), we first search for an emission line at λ ∼ 9196 Å and, if that is found, assign a potential redshift assuming it
Table 1. Observing log for the different nights and configurations used in this study. Observations were conducted with AutoFib2 (AF2) + Wide Field Fibre Optical Spectrograph (WYFFOS) on WHT using the R316R grism.

| Configuration (Pointing) | Exp. Time (Science) | Exp. Time (Sky) | # Targets (Obs/Recov.) | Date (2015) | Seeing (″) | Sky | Moon |
|--------------------------|---------------------|----------------|------------------------|-------------|-----------|-----|------|
| P1                       | 12.6 ks             | 4.1 ks         | 56 / 40                | 22 Jan      | 1.2-1.5   | Clear| Dark |
| P2                       | 13.5 ks             | 4.5 ks         | 55 / 39                | 23 Jan      | 1-1.3     | Clear| Dark |
| P3                       | 11.7 ks             | 4.1 ks         | 52 / 29                | 24 Jan      | 1.5-2.0   | Clear| Dark |
| P4                       | 12.6 ks             | 4.1 ks         | 51 / 11                | 25 Jan      | 2-3       | Clear| Dark |

Table 2. A summary of the spectroscopic sample, for all the 214 sources followed-up. We find that 212 sources are consistent with being Hα emitters at \( z \sim 0.4 \), but we separate them in different groups based on the number of lines detected and on the significance of their detections. Flag 1: Hα and at least 2 other emission lines; Flag 2: Hα and at least another emission line detected at S/N > 5; Flag 3: at least one emission line detected at S/N > 5. Flag 4: a potential Hα line but at too low S/N (S/N < 5). Note that the vast majority of Flag 4 sources are from very low S/N observations due to poor seeing, or at the lowest Hα fluxes.

| Configuration (Pointing) | Targets # | Non-Hα # | Flag 1 Hα+2L | Flag 2 Hα+1L | Flag 3 1L S/N > 5 | Flag 4 Ho low S/N | Flags 1,2,3 |
|--------------------------|-----------|-----------|---------------|---------------|------------------|------------------|-------------|
| P1                       | 56        | 1         | 29            | 2             | 9                | 16               | 40          |
| P2                       | 55        | 1         | 26            | 2             | 11               | 14               | 39          |
| P3                       | 52        | 0         | 17            | 2             | 10               | 23               | 29          |
| P4                       | 51        | 0         | 0             | 1             | 10               | 40               | 11          |
| Full Sample              | 212       | 2         | 72            | 7             | 40               | 93               | 119         |

Figure 2. The distribution of spectroscopic redshifts obtained by following up the Hα candidates in and around the cluster, compared to that expected based on the detection of the Hα line with the NB921 filter on Subaru.

is Hα. If at least two other major emission lines are found matching that redshift (e.g. [OII], Hβ, [OIII] or [NII]), we measure those positions, determine the redshift for each one, combine the measurements, and we give the source a flag of 1, as the redshift is based on 3 lines or more. The redshifts of these sources are the most robust within our sample. If we find only another strong line, we flag the source with a 2. The redshift is still considered to be robust. These sources dominate the lower flux part of the sample. If we are not able to find any other emission line apart from that found at \( \lambda \sim 9196 \) Å, we still assume it is Hα, but we flag these sources as 3. These sources are the ones with the lowest fluxes in our sample. Finally, if we fail to detect any line (this happens for cases where the estimated line flux is the weakest), we look for any other emission lines, and we follow the flag system according to the number of lines found. When no other emission lines are found and the only line found (at \( \lambda \sim 9196 \) Å) is at S/N < 5, the source is flagged as 4, and is not used at all in the analysis. There are 93 sources flagged as 4 (see Table 2), with the vast majority being sources targeted in configuration 4 (with the poorest seeing) and then configuration 3 (with the second poorest seeing). Sources from pointings 1 and 2 in this group are those with the lowest fluxes in the sample. Within our followed-up sources we find two (2) interlopers: a star and a lower redshift emitter (\( z = 0.13301 \)), with the remaining sources being very likely Hα emitters with redshifts ranging from \( z = 0.3883 \) and \( z = 0.4125 \). Our final sample is made of 119 sources with flags 1, 2, 3, and with Hα fluxes > 1.25 × 10^{-16} erg s^{-1} cm^{-2} (see Table 2).

We present the redshift distribution of those \( z \sim 0.4 \) sources in Figure 2. We also show the on-sky location of our spectroscopic sample in Figure 1, which shows that, particularly due to the different configuration set-ups, we are able to probe the full range of environmental densities (see Figure 3 and also Koyama et al. 2011).

3.4 Completeness and sample properties

Figure 4 shows the relation between Hα+[NII] flux (based on narrow-band photometry, so we can compare it with the parent NB sample) and stellar mass, for both the parent sample, and for our spectroscopic sample. The comparison with the parent sample shows that our sample recovers the full range of masses and Hα fluxes, even down to the lowest masses and also down to the lowest fluxes. Therefore, we apply no corrections, as the spectroscopic sample is consistent with
being drawn from the parent sample. We note that because of the weighting we applied when assigning the fibres, we were able to obtain a flux distribution which is much flatter than the parent sample; this allows us to have good statistics at all masses and at all H$\alpha$ fluxes/luminosities, instead of being fully dominated by e.g. the much more numerous faint H$\alpha$ emitters.

We also show the distribution of stellar masses for the samples of H$\alpha$ emitters in Figures 3 and 4. As a whole, the sample of H$\alpha$ emitters at $z = 0.41$ has a similar stellar mass distribution to samples of field H$\alpha$ emitters at similar redshifts (see Sobral et al. 2014), but with cluster H$\alpha$ emitters having higher stellar masses than H$\alpha$ emitters outside the cluster (see Koyama et al. 2013).

3.5 SFGs vs AGN in A851

Emission line fluxes are measured by fitting Gaussian profiles, and estimating the continuum directly red-ward and blue-ward of the lines (masking any other features or nearby lines). We also measure the rms directly blue- and red-ward of the lines, and assign that as the noise ($1\sigma$). In order to differentiate between star-forming and AGN, the [OII] 5007/H$\beta$ and [NII] 6583Å/H$\alpha$ line ratios are used (see Figure 5); these have been widely used to separate AGN from star-forming galaxies (e.g. Baldwin et al. 1981; Rola et al. 1997; Kewley et al. 2001, 2013). These line ratios are measured for emission lines sufficiently close to each other that dust extinction has little effect.

We note that particularly H$\beta$ can be affected by significant underlying stellar absorption and that this can be a very important effect for galaxies with relatively low EW emission lines, more characteristic of e.g. mass-selected samples, which pick up galaxies with relatively low star formation activity. By definition our sources are all high EW sources and highly star-forming. The effect of the absorption is expected to be small given the large EW. Nevertheless, we further investigate the potential effect and assess whether a correction should be applied. We use the results from Darvish et al. (2015b) which explore a redshift regime, sample and selection which are very similar to those presented in our study. The advantage is that Darvish et al. (2015b) spectra are much higher resolution and significantly deeper (as they are obtained using DEIMOS on Keck). Darvish et al. (2015b) showed that H$\beta$ Balmer stellar absorption only accounts for 5-10% correction to the H$\beta$ flux. Even the maximum 10% correction results in only $a < 0.05$ dex difference in the line ratios, smaller than our observational uncertainties. Other studies (e.g. Zahid et al. 2011; Reddy et al. 2015) also find comparable corrections for similar samples of emission-line galaxies. Given the small corrections, we decide not to correct for Balmer absorption. We note, nonetheless, that our Balmer decrements as a function of e.g. stellar mass agree very well with Garn & Best (2010), another indication that
the correction, if any, must be relatively small. However, on a source by source basis, and particularly for relatively noisy spectra, Hβ may be underestimated, leading to an over-estimation of [OIII]/Hβ. This may be happening to some of the sources above the maximal starburst line and with [NII]/Hα < 0.4.

Figure 5 shows data-points for the line ratios. We only show sources for which Hα is detected at S/N > 5 and for which we can measure emission line ratios with S/N > 2, i.e. for 89 out of 119 sources in our sample. We investigate the remaining 30 sources in our sample separately by stacking them.

Figure 5 shows curves from Kewley et al. (2001) and Kewley et al. (2013) encompassing star-forming galaxies (grey solid line), and encompassing up to maximal starbursts (blue dashed line). We use the blue dashed line to separate between what we now refer as AGN and star-forming galaxies. We find that out of the galaxies that we can classify (89 sources), 17% of our Hα emitters are consistent with having AGN activity (15 sources, 13% of full sample), while 70% (62 sources) are star-forming galaxies (see Table 3). From the remaining, 12 sources are too close to the boundary between AGN and star-forming (see Figure 5), so we label them as ‘others’ and we do not use them for the rest of the analysis. Figure 6 shows how the median stacked spectra of our AGN compares with a similar stack for our star-forming galaxies, clearly revealing the strong median differences of line ratios and line fluxes. Our stacks are all normalised to the peak of the Hα emission.

In order to further investigate the nature of the non-classifiable sources (30 sources), we stack them and measure their median properties. We stack spectra by normalising them to the peak of the Hα emission. We show the results in Figure 6 and compare them with equally stacked spectra of our clear star-forming galaxies and our AGN Hα emitters. We find line ratios which are completely consistent with a likely mix of relatively metal-poor, low mass, and moderately dust-extinguished star-forming galaxies, with lower fluxes. Our lower S/N sources show emission line properties and ratios which clearly indicate a star-forming nature, at least for the bulk of such sample. From now on, we will use our sample of clear star-forming galaxies, and our low S/N sample that we have found to be consistent with star-formation. Thus, our final star-forming sample is made of 92 likely star-forming galaxies, after rejecting AGN and those sources which are too close to the AGN selection region (see Table 3).

4 RESULTS AND DISCUSSION

4.1 AGN fraction as a function of environment

In order to investigate the prevalence of AGN among Hα emitters in and around the cluster, we evaluate the AGN fraction for different environmental densities and also as a function of cluster-centric distance. The results are presented in Figure 7. We find that the AGN fraction shows no significant correlation with increasing projected local number density nor with increasing projected cluster-centric distance (Figure 7). There is perhaps a very weak trend of increasing AGN fraction with environmental density, but for all cases at the level of < 1σ, and thus not statistically significant. This is qualitatively and quantitatively consistent with e.g. Miller et al. (2003), who found an AGN fraction of ∼20% in the local universe, independent of environment.

Our results therefore show that there is no particular prevalence of AGN at high densities and/or close to the cluster that could explain the high 24 μm/Hα as a simple consequence of higher AGN fraction at higher densities. Thus, two main explanations for the elevated 24 μm/Hα as a function of environmental density for Hα emitters still remain: dust extinction correlating with environmental density, or witnessing declining star formation histories, and thus, effectively, ‘slow’ environmental quenching. In the following sections we evaluate the properties of the star-forming pop-

Table 3. A summary of the final sample and the likely ionising sources: SFGs or AGN. For sources too close to the boundary between SFGs and AGN, we label them “Others”, and we exclude them from the analysis of SFGs. There are sources (Unclass) for which it is not possible to obtain reliable measurements of the required emission lines to classify them. We instead stack them, finding that they are fully consistent with being lower mass, lower flux SFGs.

| Classification | Number | Percentage |
|----------------|--------|------------|
| Full sample    | 119 (100%) |
| SFGs           | 62 (52%)  |
| AGN            | 15 (13%)  |
| Others         | 12 (10%)  |
| Unclass        | 30 (25%)  |
| SFGs used      | 92 (77%)  |
4.2 Properties of SFGs in and around A851 from galaxy by galaxy measurements

4.2.1 Balmer decrement: Dust extinction

The emission line ratio between Hβ and Hα is one of the most robust means of estimating dust extinction (A$_{H\alpha}$) within star-forming galaxies. The Hα/Hβ line ratio (Balmer decrement) is widely used as an extinction estimator, particularly up to $z \sim 0.4$, as it is relatively easy to obtain both emission lines. Hα/Hβ line fluxes are measured and used to estimate the extinction at Hα, A$_{H\alpha}$, by using:

$$A_{H\alpha} = \frac{-2.5k_{H\alpha}}{k_{H\beta} - k_{H\alpha}} \log_{10}\left(\frac{2.86}{H_\alpha/H_\beta}\right),$$

where 2.86 is the assumed intrinsic Hα/Hβ line flux ratio, appropriate for Case B recombination, temperature of $T = 10^4$ K and an electron density of $n_e = 10^2$ cm$^{-3}$ (Brocklehurst 1971). The Calzetti et al. (2000) dust attenuation law is used to calculate the values of $k_3 \equiv A_3/E(B - V)$ at the wavelengths of the Hα and Hβ emission lines, resulting in:

$$A_{H\alpha} = 6.531 \log_{10} H_\alpha/H_\beta - 2.981.$$

Individual measurements for high S/N Hα detections provide an average of $A_{H\alpha} = 0.9 \pm 0.9$. We also find a relation in very good agreement with Garn & Best (2010), with dust extinction increasing with stellar mass. For individual detections, we do not find a significant trend of dust extinction with environment. This could lead to the potential conclusion that the elevated 24 μm/Hα ratio may not be due to increasing dust extinction. However, using sources for which we can measure the Balmer decrement individually biases our results towards the less dust extinguished sources at all environmental densities. This can only be solved by means of stacking – see §4.3.2.

4.2.2 Metallicities

In order to investigate the metallicities of the ionised gas within the Hα emitters in and around A851, we use both [Nii]/Hα, but also O3N2. We only compute individual (source by source) metallicities for our Hα emitters in and around the cluster that have been clearly identified as star-forming galaxies. We note that in §4.3, when stacking, we remove the AGN and galaxies unclassified due to being close to the AGN selection function, but use the lower S/N galaxies, consistent with being dominated by star formation, so that we do not bias our results.
We start by using the \([\text{[Nii]}]/\text{H}\alpha\) emission line ratio. For our full sample (median stack), we find \([\text{[Nii]}]/\text{H}\alpha = 0.33 \pm 0.19\) (see e.g. Figure 6). The \([\text{[Nii]}]/\text{H}\alpha\) line ratio can be used to obtain the metallicity of our star-forming galaxies (oxygen abundance), \([12 + \log(O/H)]\), by using the conversion of Pettini & Pagel (2004):

\[
12 + \log(O/H) = 8.9 + 0.57 \times \log(N2H\alpha), \tag{5}
\]

where \(N2H\alpha\) is the line flux ratio \([\text{[Nii]}]/\text{H}\alpha\). The galaxies in our full sample (\([\text{[Nii]}]/\text{H} = 0.33 \pm 0.19\)) have a median metallicity \(12 + \log(O/H) = 8.50 \pm 0.19\), which is consistent with solar \((8.66 \pm 0.05)\), but we note that we are sampling galaxies with a large range of masses, and that we find a strong mass-metallicity relation, and thus we need to take that into account when properly comparing the samples.

We also use the O3N2 indicator (e.g. Alloin et al. 1979; Pettini & Pagel 2004) as a tracer of metallicity (the gas-phase abundance of oxygen relative to hydrogen), computed by using:

\[
12 + \log(O/H) = 8.73 - 0.32 \times \log_{10}(O3H\beta/N2H\alpha), \tag{6}
\]

where O3H\beta is the line flux ratio \([\text{[Oiii]}]/\text{H}\beta\) and N2H\alpha is the line flux ratio \([\text{[Nii]}]/\text{H}\alpha\). This indicator has the main advantages of i) using emission lines which have very similar wavelengths, thus being essentially independent of dust attenuation and ii) having a unique metallicity for each line flux ratio.

By using O3N2, we find an average metallicity of \(12 + \log(O/H) = 8.56 \pm 0.15\), thus consistent with solar and completely consistent with the \([\text{[Nii]}]/\text{H}\alpha\) metallicity for the entire sample of star-forming galaxies. For the remaining of the analysis in the paper, we will use O3N2 metallicities.

### 4.2.3 Mass-metallicity relation

We find a mass metallicity relation for both \([\text{[Nii]}]/\text{H}\alpha\) and O3N2 calibrations. The O3N2 metallicities provide a slightly steeper relation with mass, with a linear fit

\[
12 + \log(O/H;\text{O3N2}) = 0.120 \times \log_{10} M + 7.357, \tag{7}
\]

where \(N2H\alpha\) provides \(12 + \log(O/H;N2H\alpha) = 0.074 \times \log_{10} M + 7.861\). Our results are shown in Figure 8.

In Figure 8, apart from showing how metallicity correlates with stellar mass for individual star-forming galaxies in and around the cluster, we also split our star-forming galaxies according to their local densities. We thus divide the sample into three sub-samples: low density, medium density and high density. We fit mass-metallicity relations to each of the sub-samples. While we find that star-forming galaxies residing in the highest local densities have slightly higher stellar masses (consistent with e.g. Koyama et al. 2013; Sobral et al. 2013b), we find that the mass-metallicity relation is the same, within the uncertainties, for all environments. We thus conclude that, for our sample of high S/N star-forming galaxies, the mass-metallicity is independent of the local environment. The results are consistent with Sobral et al. (2013b) at \(z \sim 0.8\).

### 4.2.4 Ionisation parameter

We compute the ionisation parameter \((q_\text{ion})\) for our sample of H\alpha emitters as a whole. In order to do this, we use the ratio \([\text{[Oiii]}]/[\text{[Oii]}]\). We use equation 5 from Nakajima & Ouchi (2014) which provides \(q_\text{ion}\) as a function of \([\text{[Oii]}]/[\text{[Oii]}]\) and also takes into account the metallicity, \(12 + \log(O/H;R23)\):

\[
\log(q_\text{ion}) = \{32.81 - 1.153y^2 + \{12 + \log(O/H)\}(3.316 - 0.025y + 0.1444y^2)\} \times \{4.603 - 0.319y - 0.163y^2 + \{12 + \log(O/H)\}(0.48 - 0.027y + 0.02037y^2)\}^{-1}, \tag{7}
\]

where \(y = \log_{10}([\text{[Oii]}]/[\text{[Oii]}])\), and in this case \([\text{[Oii]}]\) is the sum of the flux of \([\text{[Oiii]}]\) 4959 and \([\text{[Oii]}]\) 5007. We find a median of \(\log(q_\text{ion}) = 7.3 \pm 0.3\), consistent with e.g. SDSS (7.18–7.51 Nakajima & Ouchi 2014). We evaluate the ionisation parameter as a function of environmental density and stellar mass in §4.3.

### 4.3 Properties of SFGs in and around A851 from stacking

Here we stack our sample in various sub-samples, to investigate relations with both local projected density and stellar mass. We present the full results in Table 4, but also show the results in Figures 9, 10 and 11. We use median stacking throughout. Prior to stacking the spectra, we normalise them to the peak of H\alpha emission. When stacking as a function of environment and stellar mass, for star-forming galaxies, we neglect AGN and sources which are too close to the AGN boundary and thus were not classified (see Table 4).

1 We correct our O3N2 metallicities to R23 by following Kewley & Ellison (2008).
Table 4. Results from our stacking analysis. We show the results for the stack of our full sample, and we further split our sample in respect to the likely ionising source. For AGN sources we do not calculate metallicities, dust extinction nor star formation rates, due to Hα being potentially contaminated by AGN activity. We split the sample in respect to stellar mass and environmental density.

| SAMPLE           | #   | [Ni]/Hα | [Oiii]/Hα | [Oii]/Hα | Mass [log_{10} M_⊙] | SFR M⊙ yr⁻¹ | 12 + log(O/H) (O3N2) | A_Hα mag |
|------------------|-----|----------|-----------|-----------|---------------------|--------------|----------------------|----------|
| Full Sample      | 119 | 0.19 ± 0.03 | 0.73 ± 0.02 | 0.34 ± 0.01 | 0.47 ± 0.03 | 9.9 ± 0.6 | 0.7 ± 0.4 | 8.45 ± 0.03 | 1.06 ± 0.08 |
| AGN only         | 15  | 0.57 ± 0.11 | 1.44 ± 0.14 | 1.25 ± 0.12 | 0.87 ± 0.03 | 9.8 ± 0.7 | —        | —        | —         |
| AGN and others   | 27  | 0.37 ± 0.06 | 1.0 ± 0.06 | 1.07 ± 0.07 | 1.07 ± 0.02 | 9.7 ± 0.7 | —        | —        | —         |
| All SFGs         | 92  | 0.17 ± 0.02 | 0.68 ± 0.02 | 0.24 ± 0.01 | 0.36 ± 0.05 | 9.9 ± 0.6 | 0.7 ± 0.4 | 8.48 ± 0.03 | 1.04 ± 0.08 |
| 8.6 < log_{10} M < 9.6 | 26  | 0.03 ± 0.03 | 0.62 ± 0.04 | 0.48 ± 0.01 | 0.78 ± 0.07 | 9.3 ± 0.3 | 0.0 ± 0.2 | 8.18 ± 0.18 | 0.35 ± 0.15 |
| 9.6 < log_{10} M < 10.0 | 21  | 0.07 ± 0.02 | 0.98 ± 0.03 | 0.28 ± 0.01 | 0.28 ± 0.18 | 9.8 ± 0.1 | 0.5 ± 0.3 | 8.36 ± 0.06 | 0.7 ± 0.15 |
| 10.0 < log_{10} M < 10.4 | 24  | 0.26 ± 0.04 | 0.78 ± 0.03 | 0.2 ± 0.01 | 0.26 ± 0.09 | 10.2 ± 0.1 | 0.9 ± 0.3 | 8.56 ± 0.03 | 1.16 ± 0.11 |
| 10.4 < log_{10} M < 11.0 | 19  | 0.3 ± 0.05  | 0.37 ± 0.02 | 0.08 ± 0.01 | 0.22 ± 0.59 | 10.6 ± 0.2 | 1.2 ± 0.2 | 8.69 ± 0.03 | 1.53 ± 0.18 |

Figure 9. Ionisation parameter from stacks as a function of environmental density (left) and stellar mass (right). Dashed lines indicate the stacked values for all sources and for star-forming galaxies only. We obtain stacks using our full sample (yielding higher ionisation parameters, due to the contribution of AGN) and using SFGs only. We find a potential rise and fall of the ionisation parameter with environment, but this is at least partially driven by the relation we find between stellar mass and ionisation parameter. The ionisation parameter has a much clearer and simple relation with stellar mass, being the highest for the lowest stellar masses, and declining with increasing stellar mass.

However, note that for one case (Figure 9), we also evaluate the ionisation parameter including AGN.

When stacking our 92 star-forming galaxies, we find a median dust extinction of A_Hα = 1.04 ± 0.08. Detailed results are presented in Table 4. We note that when stacking our spectra of star-forming galaxies (and also when stacking our full sample), we also reveal other lines, such as HeI5876 and Hγ.

The following Sections present the results of stacking as a function of stellar mass and environmental density.

4.3.1 Ionisation parameter

Our results are presented in Figure 9. We find that while the ionisation parameter seems to be very low at the lowest environmental densities (where we find the lowest star-formation rates), from log_{10} Σ_{10} > 1.6 we find a decrease of the ionisation parameter with increasing environmental density. We find the same qualitative behaviour when using either all sources or just star-forming galaxies (rejecting the AGNs leads to an overall ionisation parameter at essentially all environments).

Figure 9 (and Table 4) also shows the dependence of the median ionisation parameter as a function of stellar mass, for our Hα selected sources in and around the A851 cluster. We find that our lowest mass Hα emitters have by far the highest ionisation parameters, which is consistent with e.g. Darvish et al. (2015b). Higher stellar mass sources have lower ionisation parameters, but there is evidence that our high mass Hα emitters have higher ionisation parameters than those with a “typical” stellar mass of around 10^{10} M_⊙. We note that our sample is Hα selected, and not stellar mass selected, and that we find a strong monotonic increase of SFR with stellar mass in our stacks. Thus, for higher stellar mass galaxies, our Hα selection only picks up the actively star-forming systems, that will likely have higher ionisation potentials due to their strongly star-forming (or AGN) nature.

4.3.2 Balmer decrement: stellar mass dominates but environment matters

We evaluate the typical dust extinction (A_Hα) of star-forming galaxies from Balmer decrements in and around the cluster as a function of both stellar mass and environmental density. The results are presented in Table 4 and in Figures 10 and 11.

We find that A_Hα increases very clearly with increasing stellar mass (Figure 10), from A_Hα ~ 0.3 to A_Hα ~ 1.6 from the lowest to the highest stellar masses probed in our sample.
Our results are in very good agreement with the relation found by Garn & Best (2010), which shows no evolution up to at least $z \sim 1 - 1.5$ (e.g. Sobral et al. 2012; Ibar et al. 2013), and reveals that, statistically, stellar mass is a robust predictor of $A_{\rm H\alpha}$.

Nevertheless, Koyama et al. (2013) found that the relation provided by Garn & Best (2010) to correct for dust extinction could not reproduce dust extinction corrections implied from the ratio $24\,\mu m/H\alpha$ as a function of environmental density. In order to investigate this, we evaluate $A_{\rm H\alpha}$ as a function of environmental density in Figure 11. Our results show that $A_{\rm H\alpha}$ rises from $0.6 \pm 0.2$ at the lowest densities, to $A_{\rm H\alpha} = 1.6 \pm 0.2$ at the highest densities. Our results in Figure 11 are compared with those in Koyama et al. (2013), using $24\,\mu m$. While the trend that we see is similar, we still find a lower normalisation, but an apparently steeper slope of the typical dust extinction as a function of environmental density. This could be a consequence of the $24\,\mu m$ results being affected by some AGN contamination (which can have significant emission of hot dust). A remaining possibility is the relation used to transform $24\,\mu m/H\alpha$ ratios in $A_{\rm H\alpha}$, which is much more uncertain than Balmer decrement measurements such as the ones we obtain.

In order to further test whether the relation we see could be driven by dust extinction correlating strongly with stellar mass, we also show in Figure 11 the dust extinction expected from the relation between stellar mass and dust extinction. We compute such dust extinctions by using the median and range of stellar masses present in each bin of local environmental density. Our results show that the relation between typical dust extinction and environmental density can not be explained by stellar mass, as expected from e.g. Figure 3.

5 CONCLUSIONS

We have conducted a spectroscopic survey over a well-defined sample of Hα emitters, selected with wide-field narrow-band imaging over A551/Cl 0939+4713 at $z \sim 0.4$ (Koyama et al. 2011, 2013). We measured [OII], Hβ, [OIII], Hα and [Ni] for a sample of 119 Hα emitters in and around the A551 cluster. We also use stacking and obtain Balmer decrements, metallicities and ionisation parameters to investigate if the nature, dust properties, metallicities and other properties vary as a function of environment. Our results show that:

- About $70 \pm 13\%$ of Hα emitters in and around Abell 851 are clearly star-forming, while $17 \pm 5\%$ are AGN. We do not find any strong dependence of the AGN fraction on environment. Thus, the rise of the typical $24\,\mu m$ Hα found in Koyama et al. (2013) is not caused by a potential rise in the AGN fraction.
- We find a strong mass-metallicity at all environments, with no significant dependence on environment.
- The ionisation parameter is found to be the highest ($\log_{10}(q_{\alpha}) \sim 7.5 - 7.6$) for our lowest mass Hα emitters. While we find that the ionisation parameter falls with increasing stellar masses up to $\sim 10^{10} M_\odot$, we find that, for an Hα selected sample, the ionisation parameter starts to increase slightly again (by $\sim 0.15$ dex) with stellar mass up to $10^{11}$. This is likely a consequence of our selection, which yields active massive galaxies.
- The inclusion of AGN rises the ionisation parameter at all stellar masses and at all environments.
- We find that Hα emitters residing in the lowest densities have the lowest ionisation parameters, and that intermediate environments show Hα emitters with the highest ionisation parameters ($\sim 7.3 - 7.4$). For higher environmental...
densities we find that the ionisation parameter declines by 0.15 dex. Intermediate density environments show the highest \([\text{[OIII]}]/\text{H}\alpha\) and \([\text{[OII]}]/\text{H}\alpha\) line ratios, typically twice as large as in the highest and lowest densities.

- We find that dust extinction (\(A_\text{H}\)) correlates strongly with stellar mass, as in Garn & Best (2010), with stellar mass being the strongest predictor of \(A_\text{H}\). However, we find that our \(\text{H}\alpha\) emitters at the highest and lowest environmental densities deviate significantly from what would be predicted from their stellar masses, likely hinting that the environment still plays a key role which seems independent of stellar mass.

- Star-forming galaxies in the densest environments are found to be significantly dustier (\(A_\text{H} \approx 1 – 6\)) than those residing in the lowest density environments (\(A_\text{H} \approx 0.6\)). The correlation between \(A_\text{H}\) and environment is not driven by stellar mass, and deviates the most from what one would predict based on stellar mass at the lowest and the highest environmental densities, where likely more extreme processes may be happening.

ACKNOWLEDGEMENTS

The authors thank the anonymous reviewer for many helpful comments and suggestions which improved this work. DS acknowledges financial support from the Netherlands Organisation for Scientific Research (NWO) through a Veni fellowship and from FCT through a FCT Investigator Starting Grant and Start-Up Grant (IF/01154/2012/CP0189/CT0010). AS acknowledges financial support from NASA through the Astrophysics Data Analysis Program (ADAP), grant number NNX12AE2OG. This research has made use of NASA’s Astrophysics Data System (ADS). The authors acknowledge the award of time (W14BN20) on the William Herschel Telescope (WHT). WHT and its service programme are operated on the island of La Palma by the Isaac Newton Group in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias.

APPENDIX A: CATALOGUE OF Hα EMITTERS

Here we present the full catalogue of spectroscopically confirmed Hα emitters in and around the cluster.

This paper has been typeset from a TeΧ/LaTeX file prepared by the author.
Table A1. Hα emitters in our spectroscopic sample of 119 sources with Flags 1,2,3. We show 11 example entries: the full catalogue is published in the on-line version of the paper. AGN flags: -99 and -1: Unclass; 0: SFGs; 1: Others; 2: AGN.
