I. INTRODUCTION

The exact determination of the critical properties of a fluid (i.e., in terms of the location of its critical point and of its universality class) represents a formidable challenge both to theoretical approaches as well as to computer simulations. Although integral-equation theories are quite successful in predicting the thermodynamic and structural properties of a variety of simple and more complex systems over a wide domain in temperature-density space, they meet with variable success in the critical region due to an unsatisfactory treatment of long wave-length fluctuations which are of particular relevance in this region. To give an example, for the modified hyper-permittent chain equation (MHNC), which is amongst the most accurate liquid state theories, the boundary of the density region at which no solution is found does not correspond to the spinodal and there is no divergence of the compressibility. The mean spherical approximation (MSA), on the other hand, satisfies scaling laws in the critical region, though with peculiar critical exponents, but, similar to MHNC, fails to give a proper treatment of the first order gas-liquid (GL) transition. For computer simulations, on the other hand, suitable techniques have been developed that allow the determination of the critical point via data extrapolation from simulations performed in finite simulation volumes.

The purpose of the present paper is to examine the performance of theoretical approaches and of computer simulations in the critical region for a system where the potential \( v(r) \) is a linear combination of two interactions, exhibiting different, but well-established critical behavior, i.e., Ising 3D (IS) and mean field (MF):

\[
v(r) = v_{IS}(r) + \xi^2 v_{MF}(r).
\]

The dimensionless parameter \( \xi^2 \) indicates the relative importance of the two contributions. For reasons given below, we shall use a Coulombic interaction for \( v_{IS}(r) \) and a Kac potential for \( v_{MF}(r) \) which we define as the limit, at fixed volume \( V \),

\[
v_{MF}(r) = \lim_{\alpha \to 0} \alpha^3 \Phi(\alpha x)
\]

where \( \Phi(x) = \frac{q^2 e^{-x}}{\sigma x} \) (\( x = r/\sigma \), \( \sigma \) length scale, \( q \) has the dimension of a charge). When the dimensionless parameter \( \alpha^* = \alpha \sigma \) tends to zero the strength of the potential decreases and its range increases to infinity. It is crucial to observe that the limit \( \alpha \to 0 \) in Eq. (2) must be taken before taking the thermodynamic limit, i.e., at fixed volume. Although one might expect that the critical behavior of the system is the result of a competition between the Ising 3D and the MF behavior, leading, for example, to a cross over between the two universality classes, it turns out that the criticality of the system is described by a MF behavior except at \( \xi^2 = 0 \) where the system behaves Ising 3D like. This is unambiguously confirmed both by simulations and theory (cf. Secs. III and IV).
To overcome the problem of liquid state theories mentioned above, two advanced liquid state theories have been proposed in recent years that are able to provide accurate data in the critical region: the hierarchical reference theory (HRT) of Parola and Reatto11 and the self-consistent Ornstein-Zernike approximation (SCOZA) originally proposed by Høye and Stell12,13. Compared to standard liquid state theories they are more successful in describing the critical region, providing, in particular, non-classical (i.e., non-MF) critical exponents. The HRT approach is a successful merger14 of liquid state theory with renormalization group ideas. In the simplest form of SCOZA13,14,15 (which will be used here) the Ornstein-Zernike (OZ) equation is supplemented by an approximate, MSA-type closure relation for the direct correlation function containing a density- and temperature-dependent function which is determined by imposing self-consistency between the compressibility and internal energy routes to the thermodynamics. SCOZA predicts non-MF critical exponents16,17,18,19,20,21,22,23,24,25,26,27,28 they are different when approaching the critical temperature from above or below and, in both cases, satisfy hyperscaling20. We note that the formalism of SCOZA is not applicable for the Kac potential (i.e., for \(\alpha = 0\)) itself; instead, we rather have to consider a potential with a small, but finite parameter \(\alpha\). On the other hand, this restriction has also the attractive feature that we can study in detail how the critical behavior varies as \(\alpha\) tends to zero; indeed we can identify a cross-over behavior between a non-classical and a MF behavior.

In addition we use a recent improved mean field theory based on a loop expansion of the free energy of the RPM17,18 to describe the thermodynamic properties of our system.

Finally, we have used grand canonical Monte Carlo (GCMC) simulations performed on a hypersphere15,29, together with histogram reweighting techniques24 and finite size scaling analysis to locate the critical point and the near critical coexistence curve14,18,20,23,25,26.

With respect to the contribution to \(v(r)\) (with Ising 3D criticality we resorted to the restricted primitive model (RPM). This choice has three advantages: first, it is now well-established by simulations that the RPM belongs to the Ising 3D universality class23,24. In addition, the critical parameters (i.e., temperature \(T_c\) and density \(\rho_c\)) and the near critical coexistence curve are accurately known. Second, the reduced, dimensionless, critical temperature and density of the RPM \(T_c \approx 0.0489 - 0.0492\), \(\rho_c \approx 0.076 - 0.080\) and \(k_b T \rho_c \approx 1.13052\), \(\rho_c \approx 0.27\) which would not be the case by taking for \(v_{IS}(r)\) a short range Yukawa potential. Third, the improved MF theory outlined above can be formulated with closed expressions for a size-symmetric (and possibly charge-asymmetric) system of charged hard spheres, including thus the RPM12,15. These attractive features are contrasted by one serious disadvantage: theoretical approaches that have been proposed up to date in the literature are not able to provide results for \(T_c\) and \(\rho_c\) for the RPM that are in reasonable agreement with the predictions of simulation17,26,27,28. Nevertheless, the critical exponents we obtain from our SCOZA investigation for the RPM show a cross-over behavior to MF.

The paper is organized as follows: after presenting our model (Sec. II), we give a brief introduction to the theoretical concepts that we apply to study the critical behavior of our system: an improved MF theory and SCOZA (Sec. III); the section is closed with a comparison between the data produced by these concepts. In Section IV we give details about the simulation techniques that we apply and discuss the problems hereby encountered. In the subsequent section (Sec. V) we make a comparison between the data obtained in the theoretical approaches and in the simulations. The paper is closed with concluding remarks. An appendix provides further technical details about our reweighting procedure.

II. MODEL AND REDUCED UNITS

Using the RPM for \(v_{IS}(r)\), our potential \(v(r)\) is actually the interaction of a binary system; thus

\[
v_{ij}(r) = \begin{cases} \infty & r \leq \sigma \\ \frac{\alpha q_i q_j}{r} + \xi^2 v_{MF}(r) & r > \sigma \end{cases} \tag{3}
\]

where \(v_{MF}(r)\) is given in (2).

Numerical results will be expressed in reduced units (taking the hard-sphere (HS) diameter \(\sigma\) as unit of length): reduced temperature \(T^* = 1/\beta^*\), where \(\beta^* = q^2/k_b T \sigma\) (\(q = q_+ = q_-\) charge of the spheres, \(k_b\) Boltzmann constant, \(T\) temperature), reduced configurational chemical potential \(\mu^* = \mu/k_b T\), reduced volume \(V^* = V/\sigma^3\) and reduced density \(\rho^* = N/V^*\) (\(N\) the number of particles). However, for notational convenience we will drop the stars throughout the paper.

III. THEORY

A. Improved mean field theory (MF2L)

The Kac potential energy \(E_p(C)\) of a grand canonical (GC) configuration \(C\), assuming, for instance, periodic boundary conditions, is

\[
E_p(C) = \frac{1}{2V} \sum_{k \in \Lambda} \tilde{v}_{MF}(k) \tilde{\rho}(k) \tilde{\rho}(-k) ; \tag{4}
\]

where \(\tilde{v}_{MF}(k)\) and \(\tilde{\rho}(k)\) are the Fourier transforms of \(v_{MF}(r)\) and the microscopic density, respectively. For a fixed volume \(V\), \(\tilde{v}_{MF}(k) = \Phi(k/\alpha)\) vanishes for all non zero \((k \neq 0)\) wavevectors of Fourier space in the limit

\[
\lim_{k \to \infty} \Phi(k/\alpha) = 0.
\]
\[ \alpha \to 0 \text{ and } \bar{v}_{\text{MF}}(0) = \bar{\Phi}(0). \] Thus
\[ E_p(C) = \frac{1}{2V} \bar{\rho}(0)^2 \bar{\Phi}(0) = -2\pi q^2 V \rho^2. \] (5)
The GC partition function of the model Eq. (11) is then obtained as
\[ \Xi_V(\beta, \nu) \approx \int_0^\infty d\rho \sigma^3 \exp[-V(-\nu \rho + \beta f_{\text{RPM}}(\rho) - 2\pi \beta q^2 \xi^2 \rho^2)], \] (6)
where we have replaced the sum over the number of particles by an integral over the density which is valid for large systems and has no consequences for the thermodynamic limit (here \( \beta = 1/k_B T \)). In Eq. (11), \( f_{\text{RPM}}(\rho, \beta) \) is the Helmholtz free energy per unit volume of the RPM fluid at density \( \rho \) and \( \nu = \beta \mu \). Taking now the limit \( V \to \infty \), one gets
\[ \lim_{V \to \infty} \frac{1}{V} \ln \Xi_V(\beta, \nu) = \min \mathcal{L}(\beta, \nu, \rho), \]
\[ \mathcal{L}(\beta, \nu, \rho) = -\nu \rho + \beta f_{\text{RPM}}(\rho, \beta) - 2\pi \beta q^2 \xi^2 \rho^2. \] (7)
The function \( \mathcal{L}(\beta, \nu, \rho) \) plays the role of a Landau function. Denoting \( \beta_{\text{RPM}}^c \) the inverse critical temperature of the RPM, we note that \( \beta f_{\text{RPM}}(\rho, \beta) \) is an analytical and strictly convex function of \( \rho \) for \( \beta < \beta_{\text{RPM}}^c \) and that the critical point of our model occurs for \( \beta < \beta_{\text{RPM}}^c \). From the analysis of the Kac model it can thus be inferred that the composite system Eq. (11) will have MF behavior.\(^{9,18}\)

Equation (11) can be taken as the starting point for an improved mean field (MF) theory. To this end an approximate expression for \( f_{\text{RPM}}(\beta, \rho) \) is inserted in the Landau function \( \mathcal{L}(\beta, \nu, \rho) \) of Eq. (11) and \( \mathcal{L}(\beta, \nu, \rho) \) minimized with respect to \( \rho \) for each inverse temperature \( \beta \) and reduced chemical potential \( \nu \). At low temperatures and arbitrary \( \nu, \mathcal{L}(\beta, \nu, \rho) \) has in general two minima, \( \rho_g \) and \( \rho_t \), but there is only one value of \( \nu \), i.e. \( v_{\text{core}}(\beta) \), for which the Landau function takes equal values at the two minima. The corresponding minima are the densities of the gas and liquid phases at coexistence, respectively.

We have used for \( f_{\text{RPM}} \) the loop-expansion of the RPM free energy obtained in the field theoretical framework of Ref. \(^{17,18}\), i.e.
\[ f_{\text{RPM}} = f_{\text{RPM}}^{(0)} + f_{\text{RPM}}^{(1)} + f_{\text{RPM}}^{(2)} + \ldots \] (8)
where the superscripts \(^{(p)} \) denote the \( p \)th order contribution to the loop expansion of \( f_{\text{RPM}} \).

At the tree level one has for the RPM \(^{17}\)
\[ \beta f_{\text{RPM}}^{(0)} = \beta f_{\text{HS}}(\rho) - \rho \ln 2 - \frac{\rho}{2} \beta q^2 v_c(0), \] (9)
where \( f_{\text{HS}}(\rho) \) denotes the excess free energy per unit volume of the reference HS fluid for which the Carnahan-Starling approximation \(^{30}\) was used in numerical calculations. The \( \rho \ln 2 \) contribution stems from the entropy of mixing and \( v_c(r) \) denotes the Coulomb potential, \( v_c(r) = 1/r \) for \( r > \sigma \) and regularized inside the core region.

The one-loop contribution \( \beta f_{\text{RPM}}^{(1)} \) reads
\[ \beta f_{\text{RPM}}^{(1)} = \frac{1}{2} \int \frac{d^3 k}{(2\pi)^3} \ln \left( 1 + \beta q^2 \bar{v}_c(k) \right), \] (10)
and coincides with the free energy in the random phase approximation (RPA) \(^{34}\).

Finally, the two-loop contribution \( \beta f_{\text{RPM}}^{(2)} \), still tractable, has expression
\[ \beta f_{\text{RPM}}^{(2)} = -\frac{\beta^2}{4} \int d^3 r h_{\text{HS}, \rho}(r) \Delta^2(r), \] (11)
where \( h_{\text{HS}, \rho}(r) \) denotes the usual pair distribution function of hard spheres (HS) at number density \( \rho \); \( \Delta(r) \) the propagator of the free theory whose expression in \( k \)-space is \(^{32}\)
\[ \bar{\Delta}(k) = \frac{\bar{v}_c(k)}{1 + \beta q^2 \bar{v}_c(k)}. \] (12)

As discussed at length in Ref. \(^{17,18}\), the loop-expansion is not a systematic expansion in some small physical parameter and thus depends explicitly on the regularization of the Coulomb potential \( v_c(r) \) in the core \( r < \sigma \). In this work we adopted the MSA regularization \(^{18}\) which ensures that, at the one-loop level, the pair distribution function vanishes inside the core. Moreover, with this specification the one-loop approximation of \( f_{\text{RPM}} \) coincides with the optimized RPA (ORPA) theory or the MSA theory if one adopts, as we did, the Percus-Yevick (PY) expression \(^{32}\) for \( h_{\text{HS}, \rho}(r) \).

With the MSA regularization \(^{18}\)
\[ v_{c,\text{MSA}}(r) = \frac{1}{r} \] \( r \geq \sigma \), (13)
\[ v_{c,\text{MSA}}(r) = \frac{B}{\sigma} \left( 2 - \frac{Br}{\sigma} \right) \] \( 0 \leq r \leq \sigma \), (14)
\[ B = \frac{x^2 + x^2(1 + 2x)^{1/2}}{x^2}, \] (15)
where \( x = \kappa \sigma \) and \( \kappa^2 = 4\pi \beta q^2 \) is the Debye wavenumber squared.

**B. SCOZA**

As noted in the introduction the formalism of SCOZA is not applicable if we choose in our interaction \( v_{ij}(r) \) \( \alpha \) to be zero. Therefore we consider a slightly modified potential, \( \bar{v}_{ij}(r) \), the so-called charged Yukawa model \(^{31}\)
\[ \bar{v}_{ij}(r) = v_{ij}^C(r) + \xi^2 v_Y(r) \] \( i, j = +, - \) (16)
where \( v_{ij}^C(r) \) stands again for the RPM while the Yukawa (Y) contribution reads
\[ v_Y(r) = \begin{cases} \infty & r \leq \sigma \\ -q^2 \alpha^2 \frac{e^{-\alpha r/\sigma}}{r} & r > \sigma \end{cases} \] (17)
In the limit $\alpha^* \to 0$, $v^Y(r)$ reduces to $v^\text{MF}_i(r)$.

For this particular system the set of OZ equations,
\begin{equation}
\tilde{h}_{ij}(r) = c_{ij}(r) + \sum_k \rho_k [h_{ik} \otimes c_{kj}](r) \quad i, j, k = +, -,
\end{equation}
where '$\otimes$' denotes the convolution operation, can be decoupled: with $\rho_+ = \rho_0 / 2$ and $q_+ = -q_- = q$ and introducing the correlation functions
\begin{align}
C^Y(r) &= \frac{1}{2} [h^+ + (r) + h^-(r)] \\
C^C(r) &= \frac{1}{2} [c^+ + (r) + c^-(r)]
\end{align}
the set of OZ equations (18) decomposes into two independently solvable one-component OZ equations for the Yukawa and the Coulomb parts, namely
\begin{align}
C^Y(r) &= C^Y(r) + \rho [C^Y \otimes C^Y](r) \\
C^C(r) &= C^C(r) + \rho [C^C \otimes C^C](r).
\end{align}
The formalism of SCOZA \[34\] is based on the MSA closure to the OZ equations, i.e.,
\begin{align}
g_{ij}(r) &= 0 \quad \text{for} \quad r \leq \sigma \\
c_{ij}(r) &= -\beta v_{ij}(r) \quad \text{for} \quad r > \sigma.
\end{align}
Introducing $g^Y(r) = h^Y(r) + 1$ and $g^C(r) = h^C(r)$, leads to the MSA closure for the decoupled OZ equations \[28\]:
\begin{align}
C^Y(r) &= C^Y(r) + \rho \left[ C^Y \otimes C^Y \right](r) \\
C^C(r) &= C^C(r) + \rho \left[ C^C \otimes C^C \right](r).
\end{align}

\[28\]
For the Yukawa part the formalism of SCOZA can be applied in a straightforward way; introducing a yet unknown, state-dependent function $K^Y(\rho, T)$, the SCOZA closure relation \[28\] reads
\begin{align}
C^Y(r) &= -1 \\
C^C(r) &= C^C(r) - K^Y(\rho, T) v^Y(r) \quad r > \sigma.
\end{align}
For the Coulomb part the situation is more delicate: in Coulomb systems the Stillinger-Lovett sum-rules have to be satisfied which would be violated when introducing a function $K^C(\rho, T)$, similar to what we did for the Yukawa contribution in \[28\]. We therefore cannot extend SCOZA to the Coulomb part and have to treat it rather within MSA, i.e., we use the closure relations \[20\] for $C^Y(r)$ and $C^C(r)$.

Within the SCOZA formalism a partial differential equation (PDE) is derived that imposes thermodynamic self-consistency between the energy and compressibility routes and thus fixes the yet undetermined function $K^Y(\rho, T)$. Thus we have to calculate the internal energy and the compressibility of the system within the framework of our theory. A straightforward analysis leads to
\begin{equation}
u = \frac{u^e}{V} = 2\pi \sum_{i,j=+,-} \int d^2r g_{ij}(r) v_{ij}(r) = u^Y + u^C
\end{equation}
with $u^e$ being the excess (over HS) internal energy and introducing
\begin{equation}
u^Y = 2\pi \rho^2 \int d^2r g^Y(r) v^Y(r)
\end{equation}
and
\begin{equation}
\beta u^C = 2\pi \rho^2 \beta \int_0^\infty g^C(r) q^2 r dr = \frac{w}{4\pi \sigma^3} \left( \sqrt{1 + 2w} - 1 - w \right),
\end{equation}

\[31\]
\begin{equation}
\tilde{\chi}_{\text{red}}(= \rho k_B T \chi_T) \text{ can be calculated for our system, leading to}
\end{equation}
\begin{equation}
(\tilde{\chi}_{\text{red}})^{-1} = 1 - \frac{\rho}{2} \left[ \tilde{c}^+ + (0) + \tilde{c}^- + (0) \right] = 1 - \rho c^Y(0)
\end{equation}
\[32\]
where the tilde denotes the Fourier transform.

SCOZA imposes thermodynamic consistency between the energy and the compressibility routes via the following PDE
\begin{equation}
\frac{\partial^2 u}{\partial \beta^2} = \frac{\partial}{\partial \beta} \left( \frac{1}{\tilde{\chi}_{\text{red}}} \right).
\end{equation}
\[33\]
Using \[24\] and \[32\] and a few trivial manipulations one ends up with the following equation
\begin{equation}
B(\rho, u^Y) \frac{\partial u^Y}{\partial \beta} + D(\rho, u^C) = C(\rho) \frac{\partial^2 u^Y}{\partial \rho^2},
\end{equation}
i.e., a PDE which has a structure similar to the standard SCOZA-PDE for the one-component fluid (see e.g. Ref. \[13\]). $B(\rho, u^Y)$ is formally identical to the corresponding standard SCOZA-expression \[36\] $B(\rho, u)$, and is obtained for the present problem by simply replacing $u$ by $u^Y$; again, $C(\rho) = \rho$. Finally, one finds for the additional coefficient $D(\rho, u^C)$ the following relation:
\begin{equation}
D(\rho, u^C) = -\rho \frac{\partial^2 u^C}{\partial \rho^2}.
\end{equation}
\[35\]
Once the PDE is solved, further thermodynamic quantities (notably the pressure and the chemical potential) follow via standard thermodynamic relations.

While previous applications of SCOZA were rather dedicated to the determination of the coexistence curves and to a reliable location of the critical point within reasonable accuracy, we rather focus in the present contribution on a quantitative description of the critical properties. This means that we have to approach the critical point very closely: introducing \( \tau = (T - T_c)/T_c \), we need accurate and reliable data down to \( \tau \sim 10^{-10} \) or even less. Compared to previous SCOZA applications this requires a considerable increase in the numerical accuracy. We have realized this goal by suitable modifications of the code and by increasing the default numerical accuracy to four-fold (extended) precision. Taking these measures is in particular indispensable for small \( \alpha \) and \( \xi^2 \)-values where the Coulomb and Yukawa potentials at contact differ by many orders of magnitude. Of course this increase in numerical accuracy is accompanied by a considerable increase in computational effort.

C. Comparison between the theoretical approaches

In Figure we show the phase diagram of the system for \( \xi^2 = 1 \). We display results obtained from the improved MF theory both on the one- and on the two-loop level. We show also SCOZA results, varying the index \( \alpha \) from 1.8 down to 0.01, which – within numerical accuracy – is already very close to the Kac-limit. We observe that in this limit the SCOZA data really ‘converge’ to the results obtained within the improved MF theories. A more detailed analysis shows that for \( \alpha = 0.01 \) the SCOZA data coincide with the results obtained on the one-loop level, while there is a slight difference w.r.t. to the two-loop level. This outcome is valid for any value of \( \xi \). Although a formal proof may be difficult, the limit \( \alpha \to 0 \) of SCOZA will reproduce the exact MF result for \( h^Y(r) \) and \( e^Y(r) \) while \( h^C(r) \) and \( e^C(r) \) are solution of the MSA. The one-loop theory is precisely built with these ingredients and should coincide with SCOZA as \( \alpha \to 0 \). The MF2L theory improves \( h^C(r) \) and \( e^C(r) \) for all \( \xi \) although for \( \xi \to 0 \) the improvement is minor (cf. Sec. V). Comparison with simulation data will show that the two-loop level indeed represents an improvement. An even more elaborate version of the two-loop version of the improved MF theory that requires the pair distribution function to vanish inside the core will certainly lead to an even better agreement with simulations.

In Figure we show results obtained for the effective critical exponent \( \gamma_{\text{eff}} \) as a function of \( \tau \), obtained from SCOZA for \( \xi^2 = 0.16 \) and for a sequence of \( \alpha \)-values; \( \alpha \) varies from 1.8 down to 0.01. \( \gamma \) characterizes the divergence of the compressibility as one approaches the critical point from above, i.e., \( \chi_T \sim \tau^{-\gamma} \). The effective exponent \( \gamma_{\text{eff}} \) is obtained by differentiating the logarithm of \( \chi_T \) w.r.t. the logarithm of \( \tau \) along the critical isochore.

While in the MF universality class \( \gamma = 1 \), its SCOZA value is 2. Rather far from the critical point (i.e., for \( \tau \sim 10^{-2} \)) we observe a MF behavior; as we approach the critical point, a cross-over to the SCOZA behavior takes place. In addition, the region where the SCOZA-value is attained shrinks drastically as \( \alpha \) is lowered. This reflects that in the Kac-limit \( \alpha \to 0 \) the MF behavior becomes dominant, just as we expect it to be. The curves presented in Figure indicate that for \( \alpha = 0 \) we would observe a MF behavior over the entire \( \tau \)-range.

IV. Simulations

A. Methods

A detailed test of the validity of the theoretical approaches has been made by comparison with GCMC simulations. The GCMC simulations are performed on a hypersphere using the approach, detailed in Ref. [19,20], where the system of charged spheres is viewed as a single component fluid of charged hard spheres constrained to move at the surface of a four dimensional sphere. The practical implementation of this method, which is particularly adapted and efficient for simulating Coulomb systems of size \( N < 10000 \), can be found in Ref. [37].

Sampling of configuration space of the system is made according to the GC probability distribution

\[
\begin{align*}
\rho(N, R^N, \xi, \mu, T, V) &= \frac{V^N}{N! \Lambda^{3N} \Xi(T, V, \mu, \xi)} \exp \left\{ \frac{\beta [\mu N - U_{\text{RPM}}(R^N) - U_{\text{MF}}(N, V, \xi)]}{\Lambda^3} \right\}
\end{align*}
\]

Here \( \Xi \) is the grand canonical partition function and \( U_{\text{RPM}}(R^N) \) indicates the positions of the \( N \) charged spheres (or charged hard spheres); \( U_{\text{RPM}}(R^N) \) is the energy of the RPM comprising Coulomb and hard core interactions. The term \( U_{\text{MF}}(N, V, \xi) = -aq^2 \xi^2 N^2 \) (with \( a = 2\pi/V \)) is the MF contribution to the internal energy as explicated in Sec. IIIA.

For each value of \( \xi \), we determine the critical point and, in its vicinity, the coexistence line of the GL transition. The location of the latter is obtained from the histograms

\[
\begin{align*}
H(N, u, \xi, \mu, T, V) &= C \int dR^N \delta [u - U_{\text{RPM}}(R^N)] \rho(N, R^N, \xi, \mu, T, V)
\end{align*}
\]

where \( C \) is a constant of normalisation. By integration of \( H(N, u, \xi, \mu, T, V) \) over \( u \), one obtains the histogram \( h(N, \xi, \mu, T, V) \) which shows, in the vicinity of the GL coexistence line two peaks located at \( N = N_g \) and \( N_l \), respectively, and corresponding approximately to the densities \( \rho_g \) and \( \rho_l \) of the gas and the liquid.

At given \( T \) and \( \xi \), the values of \( \mu_c(L) \) (L characteristic size of the system defined as \( V^{1/3} \)) corresponding to GL equilibrium are affected by finite size effects. Therefore the estimates of \( \mu_c(L) \) are made for increasingly large volumes and are then extrapolated to the thermodynamic
limit. Several procedures are possible to define for a finite volume $V$ the states of GL coexistence: First one can determine $\mu_c(L)$ such that the two peaks in $h(N, \xi, \mu, T, V)$ have equal height or, preferably, equal area. This procedure, however, does not allow, at fixed $V$, a very precise location of the critical point as in its vicinity the two peaks of $h(N, \xi, \mu, T, V)$ tend to merge. A second method to locate, at fixed $V$, phase equilibrium as well as critical temperatures and densities has been proposed by Bruce and Wilding\textsuperscript{2}. It relies on the use of histograms of the variable $M = \rho - s(u - aq^2 \xi^2 N^2)/V$

\[ p(M, \xi, \mu, T, V) = \int du \sum_N \delta (M - \rho + s (u - aq^2 \xi^2 N^2)/V) + s (u - aq^2 \xi^2 N^2)/V \]  

(38)

This procedure, however, does not allow, at fixed $V$, a very precise location of the critical point as in its vicinity the two peaks of $h(N, \xi, \mu, T, V)$ tend to merge. A second method to locate, at fixed $V$, phase equilibrium as well as critical temperatures and densities has been proposed by Bruce and Wilding\textsuperscript{2}. It relies on the use of histograms of the variable $M = \rho - s(u - aq^2 \xi^2 N^2)/V$

\[ p(M, \xi, \mu, T, V) = \int du \sum_N \delta (M - \rho + s (u - aq^2 \xi^2 N^2)/V) + s (u - aq^2 \xi^2 N^2)/V \]  

(38)

For an appropriate choice of the parameter $s$, $M$ is such that at GL equilibrium and near the critical point the distribution $p(M, \xi, \mu, T, V)$ satisfies the symmetry relation

\[ p(M - \langle M \rangle, \xi, \mu, T, V) = p(-M + \langle M \rangle, \xi, \mu, T, V) \]  

(39)

expected for the order parameter that characterizes phase transitions of the Ising 3D or the MF universality class. It is remarkable that, quantitatively, the histogram $h(N, \xi, \mu, T, V)$ corresponding to the symmetrized distribution $p(M, \xi, \mu, T, V)$ has two peaks of equal area. A third possibility is to apply an unbiased finite size scaling method presented by Fisher and co-workers\textsuperscript{29-31}.

If one defines $x = \langle \delta M \rangle / \langle \delta M^2 \rangle^{1/2}$ with $\delta M = M - \langle M \rangle$, the critical temperature $T_c(L)$ is obtained by determining the values $\mu$, $s$ which enable to fit $p(x, \xi, \mu, T, V) \equiv p(x)$ to the critical distribution $p_c(x)$ of the order parameter of a system of known universality class. For example $p_c(x)$ is the distribution of magnetization of the Ising 3D model or that of the order parameter of a lattice spin model of the mean field universality class. For the Ising 3D model $p_c(x)$ is known accurately from MC simulations\textsuperscript{39} and exactly for the MF universality class (see below). The values of $T_c(L)$ obtained for increasingly large volumes $V$ can then be extrapolated to obtain $T_c(\infty)$.

From the histograms $p(x)$ obtained at fixed volume the moments $\langle \delta M^2 \rangle$ and $\langle \delta M^4 \rangle$ can be calculated and from these the fourth order cumulant, $Q_L(\beta) = \langle \delta M^4 \rangle / \langle \delta M^2 \rangle^2$, which in the vicinity of $T_c(\infty) = 1/\beta_c$ has the form\textsuperscript{30}

\[ Q_L(\beta) = Q^* + a_1 (\beta - \beta_c) L^{y_1} + a_2 (\beta - \beta_c)^2 L^{2y_2} + a_3 (\beta - \beta_c)^3 L^{3y_3} + \ldots + b_1 L^{y_1} + \ldots \]  

(40)

$Q^*$ and the exponents $y_1$ and $y_2$ are characteristic of the universality class of the system and can be determined, together with $\beta_c$, by a fit of the $Q_L(\beta)$ obtained for different system sizes.

For the MF universality class $p(x) = A \exp(-ax^2)$ with $A = [\Gamma(3/4)]^{21/4}/\pi^{3/2}$, $a = \frac{\Gamma(3/4)}{2^{3/2}}$, $Q^* = 2[\Gamma(3/4)]^{4}/\pi^2 = 0.456947$, $y_1 = d/2 = 1.5$ and $y_2 = -d/2 = -1.5$, respectively, where $d$ is the dimensionality of the system\textsuperscript{11,12}. As is well known the MF exponents do not satisfy hyperscaling.

**B. Results**

Simulations have been performed for the values $\xi^2 = 100, 11.11, 1.0, 0.1, 0.05, and 0.02$, and volumes $V = 1000, 4000, 8000$, and 16000. For each pair of $\xi^2$ and $V$ of the order of $5 - 10 \times 10^6$ MC trial moves were sampled. At volume $V = 16000$, even for such a large number of configurations the statistical error remained large so that the determination of phase equilibrium and the location of the critical point was based solely on the smaller volumes. Further, a reweighting procedure allowed to extend the results obtained at the $\xi$-values listed above to neighboring values of $\xi$ (see Appendix).

An approximate location of the GL transition inferred from the appearance of two peaks in the histograms $h(N, \xi, \mu, T, V)$ indicates that $(T_c, \rho_c)$ varies from approximately $(113, 0.25)$ at $\xi^2 = 100$ to $(0.075, 0.11)$ at $\xi^2 = 0.02$. From these values we can conclude that for the range of $\xi$ values considered the critical temperature of our model is markedly higher than the critical temperature of the RPM ($\xi^2 = 0$), i.e., $T_c \sim 0.049\textsuperscript{33}$.

It follows from the analyticity of the free energy (Sec. IIIA) that the critical behavior of our model can be analyzed according to the classical scheme (see e.g. Ref. \textsuperscript{43}). In particular, the critical exponents derived from the fit of $Q_L(\beta)$ should be MF-like and in the procedure of Bruce and Wilding\textsuperscript{2}, $p(x)$ has to be adjusted to the distribution $p_\ell(x)$ of a model with MF criticality.

In Table we summarize the critical temperatures $T_c^\xi$ estimated from the fit of $Q_L(\beta)$ calculated for the volumes $V = 1000, 4000$, and 8000 at the six values of $\xi^2$ considered in the simulations. These temperatures are in good agreement with values for $T_c(L)$ obtained at $V=8000$ by fitting $p(x)$ to the distribution $p_c(x)$ corresponding to the MF universality class. In the table $\rho_c(L)$ denotes the average density of the thermodynamic states at $\mu_c(L)$ and $T_c(L)$ corresponding to these fits.

The considered values of $\xi^2$ were too different to allow reweighting in the range of parameters $\xi^2 > 0.1$. However, it was possible to combine histograms obtained at $\xi^2 = 0.05$ and 0.1, on one hand, and those at $\xi^2 = 0.02$ and 0.05, on the other. Furthermore, the results at $\xi^2 = 0.10$ could be reweighted up to 0.13, and those at $\xi^2 = 0.02$ to 0.01. However, combination of the $H(N, u, \xi, \mu, T, V)$ was possible only at volume $V = 1000$ due to insufficient overlap of the energies at the larger volumes.

Figures 8 and 9 show the variation of $T_c(L)$ and $\rho_c(L)$ as a function of $\xi^2$ between $\xi = 0.01$ and 0.13 for $V = 1000$. GL coexistence curves are presented in Figs. 5–8 for $\xi^2 = 0.02, 0.05, 1.0,$ and 11.11 and the three volumes $V = 1000, 4000$, and 8000. The error in $T_c(L)$ is of the order of $\sim 0.3 - 0.1\%$ depending on the amount of sam-
pling of the histograms \( h(N, \xi, \mu, T, V) \). \( T_c(L) \) decreases weakly \((\sim 1\%) \) when \( V \) varies from 1000 to 8000 and differs from \( T^0 \) by about 1\%. From these results it is concluded that in the range \( 0.01 < \xi^2 < 0.13 \) the values of \( T_c(L) \) obtained by reweighting for \( V = 1000 \) provide a reliable estimate of \( T^0_c \) or \( T_c(L) \) at \( V = 8000 \) with an uncertainty of the order of \( \sim 1\% \) (cf. Table II).

The variation of the critical density with volume is small (cf. Table II), of the order of the statistical error of the order of \( \xi \). Conclusions about the universality class of a model system are summarized for the different values of \( \xi \) and \( V \), were obtained by retaining only the coexistence densities \( \rho_0(T, L) \) and \( \rho_1(T, L) \) which were closest to the critical point at \( T_c(L) \) and \( \rho_c(L) \). The coexistence densities \( \rho_0(T, L) \) and \( \rho_1(T, L) \) correspond to the two maxima of \( h(N, \xi, \mu, T, V) \) whose associated distribution \( p(x) \) is symmetric (see above). The uncertainty of the location of the maxima of \( h(N, \xi, \mu, T, V) \) increases when \( T \) approaches \( T_c(L) \) so that the error on \( \rho_c(L) \) is of the order of \( \sim 2\% \). The result for \( \rho_c(L) \) is somewhat lower than \( \rho_c(L) \) though compatible within the combined error estimates.

As mentioned previously in the literature, agreement of \( p(x) \) with a \( p_c(x) \) characteristic for a universality class, is necessary but not sufficient to make unambiguous conclusions about the universality class of a model system when studied by simulation. This uncertainty is illustrated for \( \xi^2 = 0.02 \) and \( V = 8000 \) in Fig. which shows excellent fits of both the \( p_c(x) \)'s corresponding to the Ising 3D and MF universality classes.

Although for the present model the MF universality class is implied by the analyticity in \( T \) and \( \rho \) of the free energy \( F(\xi, T, V) \) in the vicinity of the critical points determined for \( \xi^2 > 0.01 \), this critical behavior is also confirmed by the fit of the \( Q_L(\beta) \) obtained for the different values of \( V \). To realize the fits, \( Q_L(\beta) \) was calculated, for each volume, along the coexistence line by the procedure outlined above, and, for \( T > T_c(L) \), for values of \( \mu \) and \( s \) such that \( p(x) \) remained symmetric with respect to \( x = 0 \). For each volume, \( 8 \)-12 values of \( Q_L(\beta) \) were determined in the neighborhood of \( T_c(L) \). The fit is obtained by minimizing the square deviation between the simulation results at the three volumes \( V = 1000, 4000, \) and \( 8000 \) and Eq. retaining in the expression the eight parameters shown explicitly. In Table III the values of \( Q^*, \beta^* \), \( y_r \), and \( y_i \) are summarized for \( \xi^2 = 0.02, 0.05 \) and \( 0.1 \). The precision of the fits can be appreciated from Figs. Taking into account an uncertainty of \( 1 \sim 2\% \) on \( Q_L(\beta, L) \), fits compatible with this error were obtained for a wide range of values of \( Q^* \), \( y_r \), and \( y_i \), determined, respectively, with a precision of \( \sim 10 \) and \( \sim 30\% \). In contrast, the precision of \( \beta^* = 1/T_c^0 \) is \( \sim 1\% \) and of \( y_r \sim 5\% \). The value of \( y_r \) is in agreement with the MF value and, despite large uncertainties, also the values of \( Q^* \) and \( y_i \).

V. COMPARISON: THEORIES VS. COMPUTER SIMULATIONS

While the results obtained of the two theories and the simulation data have already been discussed in the respective subsections we focus in the following on a direct comparison between the theoretical and the simulation data.

To this end we go back to Table a where we have collected critical data (i.e., \( T_c \) and \( \rho_c \)) for different values of \( \xi^2 \) as obtained from the GCMC simulations, the improved MF theory, and SCOZA; in the latter case we have chosen \( \alpha = 0.01 \), i.e., a value that has turned out to be sufficiently small to make the potential \( v^N(r) \) Kac-like. From these data we can conclude that both theories are able to reproduce the critical temperatures and critical densities for large and intermediate values of \( \xi^2 \) \( \geq 1 \) very accurately. In the range of \( \xi^2 \) values \( 0.06 < 1 \) the MF2L approximation remains quantitative while SCOZA differs from the simulation results by \( \approx 10\% \) for the critical temperature and \( \approx 30\% \) for the critical density. Below \( \xi^2 \sim 0.06 \) the RPM contribution to the potential becomes dominant and we find, not surprisingly, that the theoretical data start to differ from the simulation results; in both theories, critical temperature and density tend to the MSA values of the RPM for \( \xi^2 = 0 \) whose failure to reproduce the simulation data for the RPM is well-documented. As pointed out above SCOZA identifies with the one-loop MF theory for all \( \xi^2 \) as \( \alpha \to 0 \).

The coexistence curves in the vicinity of the critical point obtained from theory and simulation are compared in Figs. for selected values of \( \xi^2 \). The convergence of the coexistence curves with system volume can be appreciated from these figures; the results obtained for volume \( V = 8000 \) appear to be close to the infinite system limit. The MF2L approximation for the coexistence curve agrees well with simulation data for \( \xi^2 > 0.1 \) but deteriorates when approaching the RPM limit where both the critical temperature and density are overestimated. One should note, however, that even at \( \xi^2 = 0.02 \) the critical temperature differs from the MC result by only \( 10\% \). The MF2L approximation is a definite improvement over either the one-loop approximation or SCOZA and could still be improved by requiring the pair distribution function to vanish inside the core at the two-loop level.

As noted above, SCOZA provides data, that are in a less satisfactory agreement with simulation data than those of the improved MF theory. Despite this deficiency, SCOZA was able to provide useful information about the critical behavior of the system: having non-classical critical exponents we have been able to trace the cross-over from a MF to a non-MF behavior, as we approach the Kac-limit (see Figure 2), verifying thus that the system displays MF criticality for \( \alpha = 0 \).
VI. CONCLUSION AND OUTLOOK

We have investigated the critical behavior of a system where the interaction is a linear combination of two potentials, each of them having a well-defined critical behavior, viz. Ising 3D or MF. Taking the RPM for the first contribution and a Kac-like potential for the latter one, we could vary via a parameter $\xi^2$ the weight of the respective contributions. Our investigations have been carried out with GCMC simulations and two theoretical approaches, i.e., SCOZA and the improved MF theory. The theoretical argument of Sec. III shows that MF behavior at the critical point is expected for all $\xi^2 \neq 0$. Indeed this conclusion can unambiguously be drawn both from simulation and SCOZA data.

We have given detailed account how the simulations and the theoretical approaches perform in the critical region. We could demonstrate that both simulations and theory have reached a level of sophistication and accuracy that allows a quantitative description of the critical behavior of simple liquids in terms of the location of the critical point as well as of the universality class. To be more specific, the location of the GL critical point (based on the MF universality class) and the coexistence lines from simulation within a numerical accuracy that allows a quantitative description of the critical behavior of simple liquids in terms of the location of the critical point as well as of the universality class. To be more specific, the location of the GL critical point (based on the MF universality class) and the coexistence lines from simulation within a numerical accuracy of $\sim 1 - 2\%$ with a slight variation with the volume $V$. For our model we find excellent agreement between theoretical approaches and computer simulations for $\xi^2$-values down to $\sim 1$; the improved MF theory, MF2L, performs in an excellent way even down to $\xi^2 \sim 0.05$. Only for very small values of $\xi^2$, i.e., close to the pure RPM, simulation data and theoretical results start to deviate. Nevertheless, SCOZA predicts the correct critical behavior, i.e., MF.

We highlight the ambiguity arising when determining critical temperatures by fitting universal critical point order distribution functions by showing that for the present system almost equally good fits are obtained for both the universal Ising 3D and MF distributions.

Finally, by referring to the theoretical developments presented in Sec. IIIA we can remark that the critical temperature is obtained by requiring that the second derivative of $L(\beta, \nu, \rho)$ with respect to the density vanishes which yields

$$\beta_c \partial^2 f_{\text{RPM}}(\rho, \beta) / \partial \rho^2 \sim \chi_T^{-1} = 2\pi \beta_c q^2 \xi^2 ,$$

where $\chi_T$ denotes the isothermal compressibility of the RPM. Arguing that for small $\xi^2$, $\chi_T \sim \left| T_c - T_c^{\text{RPM}} \right|^{\gamma}$ where $\gamma$ is the critical exponent of the compressibility of the RPM (or, more generally, that of the system with potential $\nu_{\text{HS}}$) it is concluded that

$$T_c - T_c^{\text{RPM}} \sim \xi^2 / \gamma .$$

This relation provides a means to evaluate the exponent $\gamma$. By simulation this turns out to be practical only for large systems ($V \gtrsim 20000$) which are necessary to accurately sample the density distribution function in the very low density gas phase of the RPM near the critical point.

APPENDIX: REWEIGHTING

Reweighting starts with the histograms $H_k(N, u, \mu_k, \beta_k, \xi_k)$ obtained with $N_k$ entries at fixed volume $V$, chemical potential $\mu_k$, and inverse temperature $\beta_k$ ($u = 2\pi / V$)

$$H_k(N, u, \mu_k, \beta_k, \xi_k) = \frac{N_k}{\Xi(\beta_k, \mu_k, \xi_k)} e^{\beta_k \mu_k N + \beta_k q^2 \xi^2 a N^2} \cdot \int dR^N \delta \left( u - U_{\text{RPM}}(R^N) \right) e^{-\beta_k U_{\text{RPM}}(R^N)} = \Omega(N, u) \frac{N_k}{\Xi(\beta_k, \mu_k, \xi_k)} e^{\beta_k \mu_k N + \beta_k q^2 \xi^2 a N^2 - \beta_k u} \quad (A.1)$$

With $n$ histograms ($k = 1, \ldots, n$), an estimate of the density of states $\Omega(N, u)$, up to a multiplicative constant, is given by

$$\Omega(N, u) \approx \sum_k \frac{H_k(N, u, \beta_k, \mu_k, \xi_k)}{\Xi(\beta_k, \mu_k, \xi_k) e^{F(\beta_k, \mu_k, \xi_k) + \beta_k \mu_k N + \beta_k q^2 \xi^2 a N^2 - \beta_k u - F(\beta_k, \mu_k, \xi_k) / \Xi(\beta_k, \mu_k, \xi_k) / \Xi(\beta_k, \mu_k, \xi_k)}} = \sum_k \frac{H_k(N, u, \beta_k, \mu_k, \xi_k)}{\Xi(\beta_k, \mu_k, \xi_k) e^{F(\beta_k, \mu_k, \xi_k) - F(\beta_k, \mu_k, \xi_k) / \Xi(\beta_k, \mu_k, \xi_k)}}$$

with $e^{-F(\beta_k, \mu_k, \xi_k)} = \Xi(\beta_k, \mu_k, \xi_k)$ and $e^{-F(\beta_k, \mu_k, \xi_k) / \Xi(\beta_k, \mu_k, \xi_k)} = e^{F(\beta_k, \mu_k, \xi_k) - F(\beta_k, \mu_k, \xi_k) / \Xi(\beta_k, \mu_k, \xi_k)}$.

From the knowledge of $\Omega(N, u)$ any histogram $H_j(N, u, \xi_j, \mu_j, \beta_j, V)$ can then be calculated up to a multiplicative constant, according to
\[ H_j(N, u, \beta_j, \mu_j, \xi_j) \approx \int du \sum_N \frac{e^{(\beta_j \mu_j - \beta_j \mu_k)N + (\beta_j \xi_j^2 - (\beta_j \xi_j - \beta_k \xi_j^2) a N^2 - (\beta_j - \beta_k) u) H_k(N, u, \beta_k, \mu_k, \xi_k)}}{H_k(N, u, \beta_k, \mu_k, \xi_k)} \]  

(A.2)

Using the initial guess \( f_0(\beta_k, \mu_k, \xi_k) \) for \( f(\beta_k, \mu_k, \xi_k) \), a first estimate of \( \Omega(N, u) \) is obtained from

\[ \tilde{H}(N, u, \beta_m, \mu_m, \xi_m) = \sum_n \tilde{N}_k \frac{H_k(\beta_k, \mu_k, \xi_k, N, u) + (\beta_k \xi_k^2 - \beta_m \xi_m^2) a N^2 - (\beta_k - \beta_m) u - f_0(\beta_k, \mu_k, \xi_k)}{H_k(\beta_k, \mu_k, \xi_k, N, u)} \]

where the factor \( B_m(N, u) = e^{-\beta_m \mu_m N - \beta_m q^2 \xi_m^2 a N^2 - \beta_m u} \) is introduced to prevent too large exponents in the sum \( \sum_k \) in the denominator with \( \beta_m = (\sum_{k=1,..,n} \beta_k)/n \), \( \mu_m = (\sum_{k=1,..,n} \beta_k \mu_k)/n \), and \( \xi_m = (\sum_{k=1,..,n} \beta_k \xi_k)/n \).

A new estimate of \( f(\beta_k, \mu_k, \xi_k) \) is then obtained from

\[ \int du \sum_N \tilde{H}(N, u, \beta_m, \mu_m, \xi_m) e^{(\beta_k \mu_k - \beta_m \mu_m)N + (\beta_k \xi_k^2 - \beta_m \xi_m^2) a N^2 - (\beta_k - \beta_m) u} = e^{f_1(\beta_k, \mu_k, \xi_k)} \]  

(A.3)

where \( \int du \) is a discrete sum over the energy values \( u \) effectively reached in the \( n \) MC runs. The values of \( f_1(\beta_k, \mu_k, \xi_k) \) lead to a new estimate of \( \tilde{H} \). Iteration is continued until for each \( k \) we find \( |f_k(\beta_k, \mu_k, \xi_k) - f_{k-1}(\beta_k, \mu_k, \xi_k)| < 10^{-7} \). After convergence \( \tilde{H} \) is normalized to 1. In view of the factor \( B_m(N, u) \) which relates \( \tilde{H} \) to \( \Omega(N, u) \), \( \tilde{H}(N, u, \beta_m, \mu_m, \xi_m) \) is the histogram, normalized to 1, corresponding to the average state \( \beta_m, \mu_m, \xi_m \).

From \( \tilde{H} \) one calculates the histograms \( H_k^{rew}(N, u, \mu_k, \beta_k, \xi_k) \) of states \( \beta_k, \mu_k, \xi_k \) by

\[ H_k^{rew}(N, u, \mu_k, \beta_k, \xi_k) = \tilde{H}(N, u, \beta_m, \mu_m, \xi_m) e^{(\beta_k \mu_k - \beta_m \mu_m)N + (\beta_k \xi_k^2 - \beta_m \xi_m^2) a N^2 - (\beta_k - \beta_m) u} \]  

(A.4)

Comparison of the histograms calculated by MC with those obtained by the reweighting procedure provides a valuable test of the convergence of the MC simulations.

FIGURES

FIG. 1: Phase diagram in the \((T, \rho)\)-plane of the system investigated in the present study for \(\xi^2 = 1\). Results were obtained via the improved MF theory (both one- and two-loop level) and SCOZA (for different values of \(\alpha\) – see text); lines as indicated in the legend. In addition, a line connecting the respective critical points is drawn.

FIG. 2: (Effective) critical exponent \(\gamma\) as a function of \(\tau\) (for the definition see text) of the system investigated in the present study for \(\xi^2 = 0.16\) as obtained from SCOZA for different values of \(\alpha\), lined symbols as indicated in the legend.

FIG. 3: Variation of the critical temperature \(T_c\) with strength \(\xi^2\) of the Kac potential: MF2L – squares and dashed line; SCOZA – triangles up and dashed line; solid circles – MC simulations for \(V = 1000\) (see text). The solid line is a linear fit of the simulation data. Diamond and triangle down indicate the critical temperatures of the RPM (\(\xi^2 = 0\)) obtained by the MSA approximation\(^{26}\) and simulation\(^{23,25}\), respectively.

FIG. 4: Same as Fig. 3 but for the critical density \(\rho_c\). The MC results for the RPM are from Ref.\(^{23}\) (triangles up) and Ref.\(^{25}\) (triangles right), respectively.
FIG. 5: Comparison between simulation and theoretical estimates for the coexistence curve at $\xi^2 = 100/9$ in the vicinity of the critical point. The symbols represent MC results for the different volumes: $V = 1000$ (circles), $V = 4000$ (squares), $V = 8000$ (triangles); MF2L (dashed line); SCOZA (full line).

FIG. 6: Coexistence curve at $\xi^2 = 1$ in the vicinity of the critical point. The symbols represent MC results for the different volumes: $V = 1000$ (circles), $V = 4000$ (squares), $V = 8000$ (triangles); MF2L (dashed line); SCOZA (full line); one-loop approximation (dash-dotted line).

FIG. 7: Coexistence curve at $\xi^2 = 0.05$ in the vicinity of the critical point. The symbols represent MC results for the different volumes: $V = 1000$ (circles), $V = 4000$ (squares), $V = 8000$ (triangles); MF2L (dashed line). The inset shows SCOZA (full line) and the one-loop approximation (diamonds).

FIG. 8: Coexistence curve at $\xi^2 = 0.02$ in the vicinity of the critical point. The symbols represent MC results for the different volumes: $V = 1000$ (circles), $V = 4000$ (squares), $V = 8000$ (triangles); MF2L (dashed line); SCOZA (full line); one-loop approximation (diamonds).
FIG. 9: Matching of \( p_c(x) \) Ising 3D \((T=0.07385, \mu=-9.7953, s=-1.03)\) (two peaks) and \( p_c(x) \) MF \((T=0.07477, \mu=-9.6901, s=-0.98)\) at \( \xi^2 = 0.02 \) and \( V = 8000 \).

FIG. 10: Fourth order cumulant \( Q_L(\beta) \) as a function of inverse temperature \( \beta \) at volumes \( V = 1000 \) (solid circles), 4000 (squares), and 8000 (triangles) at \( \xi^2 = 0.02 \). The straight lines are fits of the simulation data to Eq. (40).

FIG. 11: Fourth order cumulant \( Q_L(\beta) \) as a function of inverse temperature \( \beta \) at volumes \( V = 1000 \) (solid circles), 4000 (squares), and 8000 (triangles) at \( \xi^2 = 0.1 \). The straight lines are fits of the simulation data to Eq. (40).
