ABSTRACT
A previous analysis of starburst-dominated HII Galaxies and HII regions has demonstrated a statistically significant preference for the Friedmann-Robertson-Walker cosmology with zero active mass, known as the $R_0 = ct$ universe, over $\Lambda$CDM and its related dark-matter parametrizations. In this paper, we employ a 2-point diagnostic with these data to present a complementary statistical comparison of $R_0 = ct$ with $Planck$ $\Lambda$CDM. Our 2-point diagnostic compares—in a pairwise fashion—the difference between the distance modulus measured at two redshifts with that predicted by each cosmology. Our results support the conclusion drawn by a previous comparative analysis demonstrating that $R_0 = ct$ is statistically preferred over $Planck$ $\Lambda$CDM. But we also find that the reported errors in the HII measurements may not be purely Gaussian, perhaps due to a partial contamination by non-Gaussian systematic effects. The use of HII Galaxies and HII regions as standard candles may be improved even further with a better handling of the systematics in these sources.

Key words: cosmology: large-scale structure of the universe, cosmology: observations, cosmology: theory, distance scale; galaxies: general

1 INTRODUCTION
Starbursts dominate the total luminosity of massive, compact galaxies known as HIIIGx. The closely related giant extragalactic HII regions (GEHR) also undergo massive bursts of star formation, but tend to be located predominantly at the periphery of late-type galaxies. In both environments, the ionized hydrogen is characterized by physically similar conditions (Melnick et al. 1987), producing optical spectra with strong Balmer $H\alpha$ and $H\beta$ emission lines that are indistinguishable between these two groups of sources (Searle & Sargent 1972; Bergeron 1977; Terlevich & Melnick 1981; Kunth & Ostlin 2000).

Since both the number of ionizing photons and the turbulent velocity of the gas in these objects increase as the starburst becomes more massive, HIIIGx and GEHR have been recognized as possible standard candles, a rather exciting prospect given that the very high starburst luminosity facilitates their detection up to a redshift $z \sim 3$ or higher (e.g., Melnick et al. 2000; Siegel et al. 2005). The exact cause of the correlation between the luminosity $L(H\beta)$ in $H\beta$ and the ionized gas velocity dispersion $\sigma$ is not yet fully understood, though an explanation may be found in the fact that the gas dynamics is almost certainly dominated by the gravitational potential of the ionizing star and its surrounding environment (Terlevich & Melnick 1981). These sources may therefore function as standard candles because the scatter in the $L(H\beta)$ versus $\sigma$ relation appears to be small enough for HIIIGx and GEHRs to probe the cosmic distance scale independently of $z$ (Melnick et al. 1987; Melnick et al. 1988; Fuentes-Masip et al. 2000; Melnick et al. 2000; Bosch et al. 2002; Telles 2003; Siegel et al. 2005; Bordalo & Telles 2011; Plionis et al. 2011; Mania & Ratra 2012; Chávez et al. 2012, 2014; Terlevich et al. 2015).

Over the past several decades, HIIIGx and GEHRs have been used to measure the local Hubble constant $H_0$ (Melnick et al. 1988; Chávez et al. 2012), and to sample the expansion rate at intermediate redshifts (Melnick et al. 2000; Siegel et al. 2005). More recently, Plionis et al. (2011) and Terlevich et al. (2015) demonstrated that the $L(H\beta) - \sigma$ correlation is a viable high-$z$ tracer, and used a compilation of 156 combined sources, including 24 GEHRs, 107 local HIIIGx, and 25 high-$z$ HIIIGx, to constrain the parameters in $\Lambda$CDM, producing results consistent with Type Ia SNe. Most recently, we (Wei et al. 2017) extended this very promising work even further by demonstrating that GEHRs and HIIIGx may be utilized, not only to refine and confirm the parameters in the standard model but—perhaps more importantly—to compare and test the predictions of competing cosmologies, such as $\Lambda$CDM and the $R_0 = ct$ universe (Melia 2003, 2007, 2013a, 2016, 2017a; Melia & Abdelqader 2009; Melia & Shevchuk 2012).

These two models have been examined critically using diverse sets of data, including high-$z$ quasars (e.g., Kauffmann & Haehnelt 2000; Wyithe & Loeb 2003; Melia 2013b, 2014; Melia & McClintock 2015b), cosmic chronometers (e.g., Jimenez & Loeb 2002; Simon et al. 2005; Melia & Maier 2013; Melia & McClintock 2015a), gamma-ray bursts (e.g., Dai et al. 2004; Ghirlanda et al. 2004; Wei et al. 2013), Type Ia supernovae (e.g., Perlmutter et al. 1998; Riess et al. 1998; Schmidt et al. 1998; Melia 2012; Wei et al. 2015b), and Type Ic superluminous supernovae (e.g., Inserra & Smart 2014;
Wei et al. 2015a). Their predictions have also been compared using the age measurements of passively evolving galaxies (e.g., Alcaniz & Lima 1999; Lima & Alcaniz 2000; Wei et al. 2015c). A more complete summary of these comparisons, now based on over 20 different types of observation, may be found in Table 1 of Melia (2017b).

The application of HIIGx and GEHRs as standard candles has provided one of the more compelling outcomes of this comparative study involving ΛCDM and $R_h = ct$ (Wei et al. 2016). Using the combined sample of Chávez et al. (2014) and Terlevich et al. (2015), we constructed the Hubble diagram extending to redshifts $z \sim 3$, beyond the current reach of Type Ia SNe, and confirmed that the proposed correlation between $L(H\beta)$ and $\sigma$ is a viable luminosity indicator in both models. This sample is already large enough to demonstrate that $R_h = ct$ is favored over ΛCDM with a likelihood $\geq 99\%$ versus only $\leq 1\%$, corresponding to a confidence level approaching $3\sigma$.

These results, however, come with two important caveats, which partially motivate the complementary approach we are taking in this paper. Not surprisingly, the cosmological parameters are most sensitive to the high-$z$ data, so the constraints resulting from this work are heavily weighted by the high-$z$ sample of only 25 HIIGx. Given how sensitive the results are to the sub-sample of high-$z$ HIIGx data, one would want to increase the significance of this analysis by increasing the number of HIIGx-related measurements. Indeed, with the K-band Multi Object Spectrograph at the Very Large Telescope, a larger sample of high-$z$ HIIGx high-quality measurements may be available soon (Terlevich et al. 2015).

The second caveat attached to the analysis of Wei et al. (2017) is that we do not yet have a full grasp of the systematic uncertainties in the $L(H\beta) - \sigma$ correlation; these do not impact the use of HIIGx as cosmological probes. They include the burst size, its age, the oxygen abundance of HIIGx, and the internal extinction correction (Chávez et al. 2016). An example of a non-ignorable systematic uncertainty arises from the fact that the $L(H\beta) - \sigma$ relation correlates the ionizing flux from massive stars with random velocities in the potential well created by all the stars and the surrounding gas. Thus, any systematic variation in the initial mass function would alter the mass-luminosity ratio, and therefore also the zero point and slope of the relation (Chávez et al. 2014).

In spite of the fact that the high-$z$ sample of HIIGx is still relatively small, we can nonetheless further test the previous results by probing this compilation more deeply (than has been attempted before) using a two-point diagnostic, $\Delta \mu(z_i, z_j)$, defined in Equation (9) below. Quite generally, two-point diagnostics such as this differ from parametric fitting approaches in several distinct ways. They facilitate the comparative analysis of measurements in a pairwise fashion. One may use them with $n$ measurements of a particular variable to generate $n(n-1)/2$ comparisons for each pair of data. The benefits are twofold: (1) one can test how well each pair of data fits the models, and (2) assess how closely the published error bars fit a normal distribution, thereby providing some indication of possible contamination by correlated systematic uncertainties. Zheng et al. (2016) recently used such an approach to conclude that the stated errors in cosmic chronometer data are strongly non-Gaussian, suggesting that the quoted measurement uncertainties are almost certainly not based exclusively on statistical randomness (see also Leaf & Melia 2017).

As we shall see, the diagnostic $\Delta \mu(z_i, z_j)$ is expected to be zero if the model being tested is the correct cosmology. To allow for possible non-Gaussianity in the published errors, we shall use both weighted-mean and median statistics to determine the degree to which each model’s distribution of $\Delta \mu(z_i, z_j)$ values is consistent with this null result. So while Wei et al. (2016) optimized the overall ΛCDM and $R_h = ct$ parametric fits to the HII galaxy Hubble diagram, here we will test the consistency of each fit with individual pairs of data. We will begin with a brief description of the data in §2, and then define and apply the diagnostic $\Delta \mu(z_i, z_j)$ in §3. The outcome of our analysis will be discussed in §4, followed by our conclusions in §5.

2 OBSERVATIONAL DATA AND METHODOLOGY

We base our analysis on the methodology described in Chávez et al. (2012, 2014) and Terlevich et al. (2015), using their total sample of 156 sources, including 107 local HII galaxies, 24 giant extragalactic HII regions, and 25 high-$z$ HII galaxies. The correlation between the emission-line luminosity and the ionized gas velocity dispersion may be written as (Chávez et al. 2012; Chávez et al. 2014; Terlevich et al. 2015)

$$\log L(H\beta) = \alpha \log \sigma(H\beta) + \kappa,$$  
(1)

where $\alpha$ is the slope and the constant $\kappa$ represents the logarithmic luminosity at $\log \sigma(H\beta) = 0$. As noted, previous applications of this relation have produced a very small scatter in the correlation for $L(H\beta)$, making it a viable luminosity indicator for cosmology. But one cannot completely avoid its cosmology dependence because the H$\beta$ luminosity is calculated using the expression

$$L(H\beta) = 4\pi D_L^2(z) F(H\beta),$$  
(2)

where $D_L$ is the model-dependent luminosity distance at redshift $z$ and $F(H\beta)$ is the reddening corrected H$\beta$ flux.

From Equation (1), we may then obtain the distance modulus of an HII galaxy according to

$$\mu_{obs} = 2.5 \left[ \kappa + \alpha \log \sigma(H\beta) - \log F(H\beta) \right] - 100.2,$$  
(3)

with an associated error

$$\sigma_{\mu_{obs}} = 2.5 \left[ (\alpha \sigma_{\log \sigma})^2 + (\sigma_{\log F})^2 \right]^{1/2},$$  
(4)

in terms of $\sigma_{\log \sigma}$ and $\sigma_{\log F}$, these being the $1\sigma$ uncertainties in $\log \sigma(H\beta)$ and $\log F(H\beta)$, respectively. This is to be compared with the theoretical distance modulus

$$\mu_{th} = 5 \log \left[ \frac{D_L(z)}{Mpc} \right] + 25,$$  
(5)

as a function of the cosmology-dependent luminosity distance $D_L$. In ΛCDM, the luminosity distance may be written

$$D_L^{\Lambda C D M}(z) = \frac{ct}{H_0} \frac{(1+z)}{\sqrt{\Omega_k}} \times \sinh \left( \sqrt{\Omega_k} \frac{1}{2} \times \int_0^z \frac{dz}{\sqrt{\Omega_m(1+z)^3 + \Omega_\Lambda (1+z)^3 + \Omega_k (1+z)^{3\Omega_k+1} + \Omega_d (1+z)^{3\Omega_d+1} + \Omega_{w,0} (1+z)^{3\Omega_{w,0}+1}}} \right).$$  
(6)

where $p_{obs} = w p_{obs}$ is the dark-energy equation of state; radiation is ignored in the local Universe. Also, $\Omega_i = \rho_i / \rho_c$, for matter (m), radiation (r) and dark energy (de), while $\Omega_k = 1 - \Omega_m - \Omega_\Lambda$ incorporates the spatial curvature of the Universe, and $\Omega_d$ is sinh when $\Omega_k > 0$ and sin when $\Omega_k < 0$. Today’s critical density is $\rho_c \equiv 3H_0^2 / 8\pi G$. Since we are here assuming a flat Universe, (i.e., $\Omega_k = 0$), the right side of this equation becomes $(1 + z)c/H_0$ times the integral. For the $R_h = ct$ cosmology (Melia 2003, 2007, 2013a, 2016a, 2016b; Melia & Abdelsadeq 2009; Melia & Shevchuk 2012), the luminosity distance is given by the much simpler expression

$$D_L^{R_h=ct}(z) = \frac{c}{H_0} (1+z) \ln(1+z).$$  
(7)
Here we follow Wei et al.’s. (2015b, 2016) approach and circumvent circularity issues by optimizing the coefficients \( \alpha \) and \( \kappa \) individually for each model, via maximization of the likelihood function. With this approach, \( H_0 \) and \( \kappa \) are not independent of each other; one may vary either \( H_0 \) or \( \kappa \), but not both. For the purpose of maximizing the likelihood function, it is therefore useful to define a combined parameter,

\[
\delta \equiv -2.5 \alpha - 5 \log H_0 + 125.2 ,
\]

where \( \delta \) is the “Hubble-free” logarithmic luminosity and the Hubble constant \( H_0 \) is in units of \( \text{km s}^{-1} \text{Mpc}^{-1} \). The constants \( \alpha \) and \( \delta \) are statistical “nuisance” parameters, analogous to the adjustable quantities, however, we simply use the Planck function. With this approach, \( H_0 \) can be obtained for each model, via maximization of the likelihood function, it is therefore useful to define a combined parameter.

\[
\Delta \mu(z_i, z_j) = \frac{-\delta + 2.5 \alpha \log \sigma_i - 2.5 \log F_i - \delta + 2.5 \alpha \log \sigma_j - 2.5 \log F_j}{5 \log \frac{D_L(z_i)}{1 \text{ Mpc}} - 5 \log \frac{D_L(z_j)}{1 \text{ Mpc}}} 
\]

is expected to be zero for any pair of HII data at redshifts \( z_i \) and \( z_j \) if the cosmology used to calculate \( D_L \) is correct. As one can see, the value of \( H_0 \) does not affect this constraint and is absorbed into the optimized coefficient \( \delta \). For the sake of normalizing the various quantities, however, we simply use the Planck value 67.74 kg s\(^{-1}\) Mpc\(^{-1}\) throughout this analysis.

Notice in passing that \( \alpha \) and \( \delta \) are similar between the different cosmologies, varying between them by \( \leq 4\% \), i.e., well within 1\( \sigma \). Thus, since \( H_0 \) is also not a factor in \( \Delta \mu(z_i, z_j) \), Equation (9) represents a powerful diagnostic for comparing the viability of different models. The application of this 2-point diagnostic will be described in the next section.

Finally, to improve the statistics even further, we have removed seventeen points (including one GEHR source at \( z=0.00001 \)) from our complete sample whose measurement places them more than 3\( \sigma \) away from the best fit curves. We have also chosen to remove the other GEHR source at \( z=0.00001 \). While this point is only 2\( \sigma \) from the best fit curve, it is the lowest-redshift measurement in the catalog, which, by the nature of 2-point diagnostics, causes it to drastically alter the statistical results. These anomalous points are identical for all three models, so their removal does not bias either of them. The final reduced sample therefore contains 138 measurements that are used to determine the best fits reported in Table 1. The eighteenth eliminated sources are the two GEHRs at \( z=0.0001, \) and J162152+151855, J132347-013252, J211527-075951, J002339-094848, J094000+203122, J142342+225728, J094252+354725, J094254+340411, J001647+104742, J002425+140410, J103059+094516, J003218+150014, J105032+153806, WISP173-205, J084000+180531, and Q2343-BM133.

### Table 1. Parameters optimized via maximization of the likelihood function

| Model       | \( \alpha \)       | \( \delta \)       | \( \Omega_m \)    | \( \Omega_{de} \) | \( w_{de} \) |
|-------------|-------------------|-------------------|-------------------|-------------------|-------------|
| \( R_0 = c \) | 4.78\(^{+0.07}_{-0.09} \) | 32.01\(^{+0.32}_{-0.30} \) | -                 | -                 | -           |
| Planck ΛCDM | 4.86\(^{+0.08}_{-0.08} \) | 32.27\(^{+0.22}_{-0.21} \) | 0.3089            | 1.0 - \( \Omega_m \) | -1          |
| ΛCDM       | 4.86\(^{+0.09}_{-0.10} \) | 32.27\(^{+0.34}_{-0.36} \) | 0.32\(^{+0.09}_{-0.06} \) | 1.0 - \( \Omega_m \) | -1          |

3 APPLICATION OF THE TWO-POINT DIAGNOSTIC

As discussed in more detail in Leaf & Melia (2017), the use of two-point diagnostics necessitates special care when analyzing the statistics they produce. First, the weighted mean of all \( n(n-1)/2 \) \( \Delta \mu(z_i, z_j) \) values may be calculated using the expression

\[
\mu = \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} \Delta \mu(z_i, z_j) / \sigma^2_{\Delta \mu_{ij}}}{\sum_{i=1}^{n} \sum_{j=1}^{n} 1 / \sigma^2_{\Delta \mu_{ij}}} ,
\]

in which \( \sigma_{\Delta \mu_{ij}} \) is the error for a single application of Equation (9), found using standard error propagation. The error in the mean, however, must be calculated by carefully considering the correlation introduced from the repeated use of individual points in different pairs. For this purpose, we rewrite the weighted mean in the equivalent form

\[
\mu = \frac{\sum_{i=1}^{n} \beta_i M(z_i)}{\sum_{i=1}^{n} \sum_{j=1}^{n} 1 / \sigma^2_{\Delta \mu_{ij}}} ,
\]

with each \( \beta \) value given by the expression

\[
\beta_i = \frac{\sum_{j=1}^{N} 1 / \sigma^2_{\Delta \mu_{ij}} - \sum_{k=1}^{N} 1 / \sigma^2_{\Delta \mu_{ik}}}{N} .
\]

In addition, we have defined the quantity

\[
M(z_i) = \frac{-\delta + 2.5 \alpha \log \sigma_i - 2.5 \log F_i}{5 \log \frac{D_L(z_i)}{1 \text{ Mpc}}} 
\]

With the values of \( \beta \) thus calculated, the variance then follows and is given as

\[
\Delta \sigma^2_{\text{w.m.}} = \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} \sigma^2_{\Delta \mu_{ij}}}{\left( \sum_{i=1}^{n} \sum_{j=1}^{n} 1 / \sigma^2_{\Delta \mu_{ij}} \right)^2} .
\]
Knowing the standard deviation of the mean, we now have a measure of the consistency of the measurements with a given model. In the case of the \( \Delta \mu \) diagnostic, we expect the weighted mean to be statistically consistent with zero if the applied model is the correct cosmology. Note that we do not introduce the errors in the fitted parameters in this analysis. This is due to the error affecting both halves of the two-point diagnostics in a very similar manner. That is, if the value of \( \sigma \) is slightly too low, it would have the effect of reducing both ‘single-points’, the net effect of which ends up being statistically insignificant.

When non-Gaussian errors are suspected, however, such situations motivate the use of ‘median statistics,’ pioneered by Gott et al. (2001), in which error propagation is neither required nor assumed. This approach takes advantage of the fact that for any measurement based on some distribution function, there is a 50% chance of it being above the true median of the underlying distribution, without any need to know its form. Thus, for \( N \) ranked measurements, the true median has a probability

\[
P_i = \frac{2^{N-N!}}{i!(N-i)!}
\]

(i.e., the binomial distribution) of being found between measurements \( i \) and \( i + 1 \). One can use this to construct confidence regions about the median of the data, analogous to a standard deviation in Gaussian statistics, and assign to them a formal probability of finding the true median of the underlying distribution. However, it would be incorrect to apply this to, say all \( n(n - 1)/2 \) diagnostics at once, for the same reasons noted in Leaf & Melia (2017). The fact that each measurement contributes to \( N-1 \) diagnostics means that the data are correlated: as a result, a single measurement can move the median farther than in the case where the 2-point values are truly randomly distributed.

We propose a remedy that takes advantage of the binomial properties of the median, but instead of considering all the diagnostics simultaneously, we construct a random sub-sample, in which each realization of the diagnostic is used exactly once, except for the one that was omitted. Therefore none of the diagnostic values is used more than once, completely avoiding any possible correlation. Following this, we record the median of the diagnostics of this uncorrelated sample, as well as the standard deviation of the realization. Next, we generate a large number (here, 1 million) of these realizations, and report the overall median of all the individual medians in Table 2.

In Table 2, we also report the standard deviation of the median. This value is different from the overall standard deviation of the set of all 1 million medians. It is fundamentally related to the error in the mean of any set of data, in that it is some distinct factor smaller than the standard deviation of the data, dependent on the size of the data set. However, the exact relationship that exists between the standard deviation of the medians and the number of sources used to determine the median of all the realizations is not empirically known.

In order to address this deficiency, we have have used the following approach, based on Monte-Carlo simulations with mock data to find this relationship to reasonable accuracy. We construct a mock data set by drawing at random from some probability distribution function, with the same number (i.e., 138) of points as in the real data set. Then, we construct a random set of 2-point diagnostics following the same method used with the real data. We record the median and standard deviation of the realization, repeating this process a sufficiently large number of times (say, 20,000). Then, we repeat the process with a new random set of mock data drawn from the same distribution, and repeat this 5,000 times. Next, we determine the standard deviation of the set of 5,000 medians, as well as the mean of the 5,000 standard deviations. Finally, we compare the actual standard deviation of the median of all realizations with the mean of the standard deviations of each realization. We run this simulation with three different probability density functions—a

\[
\begin{array}{c}
4 \quad \text{Leaf & Melia} \\

\end{array}
\]

**Figure 1.** Unweighted histogram of all 9,453 \( \Delta \mu \) diagnostic values for the \( R_0 = ct \) universe (see Eq. 9). The \( y \)-axis gives the number of diagnostic values per bin.

**Figure 2.** Same as fig. 1, except now for Planck \( \Lambda \)CDM.

**Figure 3.** Same as fig. 1, except now for \( \Lambda \)CDM with a re-optimized value of \( \Omega_m \) (see Table 1).
normal distribution, a skew normal distribution with shape parameter $\alpha=4$, and a flat distribution over an interval. In all three cases the relationship between the standard deviation of the median and the mean standard deviation of each realization is found to be statistically consistent, and apparently dependent only on the number of sources chosen.

For a sample of 138, the multiplicative factor is 1.822, always yielding a standard deviation of the medians smaller than the mean of the standard deviations by this factor. The values reported in Table 2 for the standard deviation of the median are therefore determined by taking the standard deviations of the million medians and dividing them by the corresponding factor. While this does technically include an implicit assumption that all data are sampled from a single underlying statistical distribution, we argue that by focusing on the median of these (instead of the mean), and the fact that there must certainly exist a single true cosmological model, this assumption is reasonable.

The two-point diagnostic we have introduced in Equation (9) is expected to be zero for the correct cosmology. The degree by which a given model’s median is consistent with zero is therefore a measure of its consistency with the observations. We discuss the results of this analysis in the next section.

4 DISCUSSION

In Table 2 and figs. 1-6 we report the results of both our weighted-mean and median statistical analyses, described in §§ 2 and 3 above. One of the principal benefits of 2-point diagnostics constructed with regard to redshift ordering lies not only in determining how well a set of data fits a model, as revealed, e.g., with the use of information criteria but, also in providing insight into whether or not the low-$z$ sources are consistent with the same model as that preferred by the higher-$z$ sources.

Our complete sample of 138 sources constitutes the original 156 minus the 18 outliers, as detailed in § 2. As one can see from Table 1, the optimized value of $\alpha$ is about 4.8 in every case, statistically consistent with the results of previous analyses by Chávez et al. (2012, 2014), Terlevich et al. (2015), and Wei et al. (2016). For these 138 measurements, we constructed for each model the 9453 unique 2-point diagnostics and calculated the weighted mean and corresponding 1-$\sigma$ error based on the reported uncertainties (see figs. 1-3 for the complete unweighted histograms). For the $R_0 = ct$ universe (fig. 4), the weighted mean is found to be consistent with zero at about 1-$\sigma$. There is mild tension for Planck $\Lambda$CDM (fig. 5) and the best-fit $\Lambda$CDM cosmology (fig. 6), however, in that the weighted mean is inconsistent with zero at about 1.5$\sigma$ (compare the entries in columns 2, 3 and 4 of Table 2). Perhaps more importantly, fewer than the expected 68.3\% of the diagnostics lie within 1-$\sigma$ of the weighted mean (column 5) for all three models, implying that the reported errors are probably not purely Gaussian and that there may be an additional source of error not accounted for in this analysis.

It is therefore helpful to circumvent this possible non-Gaussianity by also analyzing the 2-point diagnostics using median statistics, as described above. With this approach, the three models show a similar inconsistency with a zero median (columns 6, 7 and 8 of Table 2), with a negative value in every case, roughly 1.3$\sigma$ different from zero. The fact that both the weighted mean and the median are negative for all the models suggests that the luminosity distance at low-$z$ is generally greater than that predicted by these cosmologies, or that it is smaller than expected at high-$z$. The implication is that either (i) none of the models are completely correct, or (ii) there may be some systematic problems with the data at high-$z$ (or more likely) at low-$z$. Thus, while a discrepancy smaller than 2$\sigma$ may not be definitive, it nonetheless motivates further analysis involving a possible contamination by non-Gaussian systematic errors.

Along these lines, we point out that some authors have speculated on the possibility that a local “Hubble bubble” (Shi 1997; Keenan et al. 2013; Romano 2016) might be influencing the local dynamics within a distance ~ 300 Mpc (i.e., $z \leq 0.07$). If true, such a fluctuation might lead to anomalous velocities within this region, causing the nearby expansion to deviate somewhat from a pure Hubble flow. This effect could be the reason we are seeing a slight negative bias for the weighted mean and median of the 2-point diagnostic for every model, since nearby velocities would be slightly larger than Hubble, implying larger than expected luminosity distances at redshifts smaller than ~ 0.07. In addition, the existence of local peculiar velocities would imply that the errors associated with low-$z$ measurements should be bigger than quoted, increasing the number of 2-point diagnostics that fall within 1-$\sigma$ of the expected dispersion, possibly ‘filling’ the distributions in figs. 1-3 sufficiently to produce entries in column 5 of Table 2 closer to the value (~ 68.3\%) expected of a true Gaussian distribution.

5 CONCLUSIONS

The totality of the results shown in Tables 1 and 2, and illustrated in figs. 1-6, supports the use of HII Gx and GEHR sources as standard candles for cosmological testing, though the analysis based on
2-point diagnostics has probed the measurement errors in greater detail than was possible solely via parametric fits to the data, the subject of our previous paper on this subject (Wei et al. 2016).

In this paper, we have proposed a new 2-point diagnostic for analyzing HIIGx and GEHR data with the inclusion of median statistics, which circumvents the need for assuming Gaussian errors in the measurements. This approach may be used alongside, and compared, with the better understood weighted mean method. We have shown that these two types of analysis give generally consistent results, insofar as the HI data are concerned. Broadly speaking, one of the principal conclusions of this analysis is that employing the entire compilation of HIIGx and GEHR sources (with the exception of several outliers) produces slight tension between the cosmological parameters favoured by the data at low and high redshifts. We believe this is circumstantial evidence in support of the proposal by Shi (1997), Keenan et al. (2013) and Romano (2016) of a dynamical influence due to a local Hubble bubble extending out to $z \sim 0.07$, which produces local peculiar velocities comparable to those in the Hubble flow at low redshifts.

Nonetheless, probing the HIIGx and GEHR data with 2-point diagnostics has not changed the essential conclusions drawn by Wei et al. (2016), whose cosmological tests based on these sources favoured the $R_0 = ct$ model over $Λ$CDM. Our comparison using the HI sample has shown that $R_0 = ct$ is favoured over both Planck $Λ$CDM and $Λ$CDM with a variable $Ω_m$, at least when viewed in terms of weighted mean statistics. The caveat, however, is that an approach based on median statistics produces less differentiation between the three models.

In addition, we have found in all cases that our 2-point diagnostic with the weighted mean approach yields fewer values within individual 1σ error regions than the 68.3% required of a true Gaussian distribution. This may be an indication that the reported errors are not purely statistical, which may happen, e.g., when the uncertainties are contaminated by systematic effects, including at least a partially non-Gaussian component, or when there is an additional source of uncertainty, other than what we considered in this analysis.

ACKNOWLEDGMENTS

We are very grateful to the anonymous referee for providing valuable insights and suggested improvements to the manuscript. FM is supported by Chinese Academy of Sciences Visiting Professorships for Senior International Scientists under grant 2012T1J0011, and the Chinese State Administration of Foreign Experts Affairs under grant GDJ20120491013.
