Abstract

In a first course of general relativity, it is usually quite difficult for students to grasp the concept of a geodesic. It is supposed to be straight (auto-parallel) and yet it ‘looks’ curved. In these situations, it is very useful to have some explicit examples available which show the different behaviour of geodesics. In this paper, we present GeodesicViewer, an interactive tool for studying the behaviour of geodesics in many different spacetimes. The geodesics can be represented in several ways, depending on the spacetime in question. The use of a local reference frame and ‘Cartesian-like’ coordinates helps the students to develop some intuition in various situations. We present the various features of GeodesicViewer in the form of readily formulated exercises for the students.

(Some figures in this article are in colour only in the electronic version)

1. Introduction

The intrinsic curvature of a spacetime in general relativity is a concept that contradicts our every day experience of space and time. The necessary mathematical set of tools is difficult to learn and fairly abstract. To get some impression of what a curved spacetime means, the behaviour of light rays and particles in free motion is studied. In the geometric optics limit and for particles whose mass has no back-reaction on the curvature of spacetime, light rays and particles in free motion can be represented by null and time-like geodesics, respectively.

For a first glimpse on how null and time-like geodesics behave, it may be sufficient to use off-the-shelf/standard software such as, for example, Maple, Mathematica or Octave. All of these could integrate the geodesic equation and show the geodesic as a 2D or 3D plot. However, to explore the behaviour of geodesics, an interactive tool is indispensable.
In this paper, we present GeodesicViewer [1], an interactive tool to thoroughly examine the behaviour of light-like and time-like geodesics in a spacetime whose metric is provided analytically. The database of metrics is taken from the Motion4D library [2]. The metrics with the corresponding Christoffel symbols and local tetrads are detailed in [3]. The graphical user interface, see figure 1, is written using the object-oriented, cross-platform application framework Qt. The graphical 2D and 3D output is realized by means of the Open Graphics Library (OpenGL). For the numerical integration of the geodesics, we use a standard fourth-order Runge–Kutta method and the integrators of the GNU Scientific Library (GSL).

This paper is organized as follows. In section 2, we give a short description of GeodesicViewer. Section 3 discusses the standard situations in the Schwarzschild spacetime. Periodic orbits of time-like geodesics in black hole spacetimes are worked out in section 4. Sections 5 and 6 deal with the more exotic spacetimes like the Morris–Thorne wormhole and the extreme Reissner–Nordström diblack hole.

GeodesicViewer is freely available for Linux and Windows. The source code and several examples can be downloaded from www.vis.uni-stuttgart.de/relativity.

2. GeodesicViewer

The two main outputs of GeodesicViewer are 3D and 2D representations of the geodesic data. In the standard 3D representation, a geodesic is depicted by means of pseudo-Cartesian coordinates, where the inherent coordinates are transformed into Cartesian coordinates as usual. If an embedding diagram is defined for a specific hypersurface of the spacetime, the geodesic can also be represented in this form. (In principle, the user can implement

---

4 An LGPL version of Qt can be downloaded from http://qt.nokia.com/.
5 Details about OpenGL can be found on http://www.opengl.org/.
6 GNU Scientific Library (GSL) can be downloaded from http://www.gnu.org/software/gsl/.
any representation he wants.) The standard 2D representation of a geodesic is also given in pseudo-Cartesian coordinates, where now only a specific hypersurface is used. Another representation shows coordinate or velocity relations. For example, the radial coordinate could be plotted against the affine parameter. A third representation follows from the Euler–Lagrangian formalism, where an effective potential can be defined. This representation is particularly helpful to find bound orbits.

The numerous features of GeodesicViewer are described by means of examples which are formulated as exercises. The mathematical explanations are directed to the teacher. The exercises can either be made from scratch or a configure file can be prepared in advance, so that the student only has to change a few parameters. Each result description is accompanied by a configure file which holds the final result for reproduction in GeodesicViewer. To familiarize oneself with the graphical user interface of GeodesicViewer, there are several online tutorials. These can be worked through either alone or with guidance from the teacher.

3. Basic examples in the Schwarzschild spacetime

The prime example of general relativity is the Schwarzschild metric which we will give here in isotropic coordinates \( x^\mu = (t, x, y, z) \). The line element \( ds^2 = g_{\mu\nu} dx^\mu dx^\nu \) reads

\[
0 = \ddot{t} + 2 \Gamma^t_{tx} \dot{t} \dot{x} + 2 \Gamma^t_{ty} \dot{t} \dot{y},
\]

\[
0 = \ddot{x} + \Gamma^x_{tt} \dot{t}^2 + \Gamma^x_{tx} \dot{t} \dot{x} + 2 \Gamma^x_{xy} \dot{t} \dot{y} + \Gamma^x_{yy} \dot{y}^2,
\]

\[
0 = \ddot{y} + \Gamma^y_{tt} \dot{t}^2 + \Gamma^y_{tx} \dot{t} \dot{x} + 2 \Gamma^y_{xy} \dot{t} \dot{y} + \Gamma^y_{yy} \dot{y}^2,
\]

with the Christoffel symbols

\[
\Gamma^t_{tx} = \frac{2 \rho \dot{x}}{\rho^3 \left[ 1 + \rho_s/\rho \right]^2}, \quad \Gamma^t_{ty} = \frac{2 \rho \dot{y}}{\rho^3 \left[ 1 + \rho_s/\rho \right]^2},
\]

\[
\Gamma^t_{tt} = \frac{2 \rho^3 (\rho - \rho_s)}{(\rho + \rho_s)^3}, \quad \Gamma^t_{tx} = \frac{2 \rho \dot{x}}{\rho^3 \left[ 1 + \rho_s/\rho \right]^2},
\]

\[
\Gamma^x_{xx} = \Gamma^y_{yy} = -\Gamma^x_{yy} = -\Gamma^y_{xx} = -\frac{2 \rho \dot{x}}{\rho^3 \left[ 1 + \rho_s/\rho \right]},
\]

\[
\Gamma^y_{yy} = -\Gamma^y_{xx} = \Gamma^x_{xy} = -\frac{2 \rho \dot{y}}{\rho^3 \left[ 1 + \rho_s/\rho \right]}.
\]

Here, a dot represents the derivative with respect to the affine parameter \( \lambda \); hence \( \dot{i} = dr/d\lambda \).

To integrate the geodesic equations, we need not only an initial position but also an initial direction. For this purpose, we first introduce the local reference frame \( \{ e_{(i)} \} = \{ e_t, e_x, e_y \} \) of an
observer which defines a local Minkowskian system. The four base vectors \( e^{(i)} = e^\mu_{(i)} \partial_\mu \) have to fulfil the orthonormality condition \( g_{\mu\nu} e^{(i)}_\mu e^{(j)}_\nu = \eta^{(i)(j)} \) with \( \eta^{(i)(j)} = \text{diag}(-1, 1, 1, 1) \). Here, the most convenient choice for the local reference frame is the one which is adapted to the coordinates and the symmetries of the metric,

\[
e^{(t)} = \left( 1 + \frac{\rho_s}{\rho} \right)^{-2} \partial_t, \quad e^{(x)} = \left( 1 + \frac{\rho_s}{\rho} \right)^{-2} \partial_x, \quad e^{(y)} = \left( 1 + \frac{\rho_s}{\rho} \right)^{-2} \partial_y, \quad e^{(z)} = \left( 1 + \frac{\rho_s}{\rho} \right)^{-2} \partial_z.
\]

Now, an initial direction, \( k = k^{(i)} e^{(i)} \), of a null or a time-like geodesic can be defined with respect to this local reference frame as shown in figure 2.

For a null geodesic we have \( k = k^{(0)} e^{(0)} + \sin \chi \cos \xi e^{(1)} + \sin \chi \sin \xi e^{(2)} + \cos \chi e^{(3)} \). The initial direction of a time-like geodesic, on the other hand, equals the initial four-velocity \( k = u = \gamma c \left( 1 + \frac{\rho_s}{\rho} \right)^{-2} \partial_t + \gamma \beta c \left( \sin \chi \cos \xi e^{(1)} + \sin \chi \sin \xi e^{(2)} + \cos \chi e^{(3)} \right) \), where \( \beta = \frac{v}{c} \) is the initial velocity \( v \) scaled by the speed of light, and \( \gamma = \frac{1}{\sqrt{1 - \beta^2}} \). Because we restrict ourselves to geodesics in the \( xy \)-plane, we must set \( \chi = 90^\circ \). The geodesic equations can now be solved using the initial position \( x^{\mu}|_{\lambda=0} \) and the initial direction \( \dot{x}^{\mu}|_{\lambda=0} = k^{\mu} \).

The numerical integration of the geodesics is accomplished by either a standard fourth-order Runge–Kutta method or the integrators of the GSL. After each integration step, the geodesic is tested if it still fulfils the constraint equation \( g_{\mu\nu} \dot{x}^\mu \dot{x}^\nu = \kappa c^2 \) with \( \kappa = 0 \) for light-like and \( \kappa = -1 \) for time-like geodesics. If this constraint is not fulfilled within a certain accuracy, the integration stops.

For the following examples, we set \( G = c = M = 1 \). In physical units, this means that \( G/c^2 = 1 \text{ls}/\text{cM} \) which equals 1 light second per mass unit \( \text{cM} \approx 2.03 \times 10^5 M_\odot \). Hence, \( M = 1 \) represents an object of \( 2.03 \times 10^5 \) solar masses and distances are measured in light seconds.

### 3.1. Deflection of light

In the neighbourhood of a black hole, light rays are no longer straight lines but they are deflected due to the curvature of spacetime. The size of the deflection depends on how close the light ray passes the black hole.
Exercise: Start GeodesicViewer and select the Schwarzschild metric in isotropic coordinates (SchwarzschildIsotropic) in the ‘Metric/Integrator/Constants’ window. Set the position of an observer in the ‘Local Tetrad’ window to \((t = 0, x = 6, y = 6, z = 0)\). With respect to his local reference frame, the observer starts light rays in the negative \(y\)-direction, \(k = e_0 = e_2\). For that, set the direction angle \(\xi = 180^\circ\) within the ‘Geodesic’ window. Modify the initial position \(y\) and describe the behaviour of the light rays. What is the closest approach where the light ray can still escape from the black hole?

Result: Figure 3 shows light rays for several initial positions \(y_i\). The closer the light ray passes the black hole, the stronger the rays are deflected. If the light ray crosses the photon orbit, \(r_{po} = \frac{3}{2}r_s (\rho_{po} = (2 + \sqrt{3})\rho_s)\), the light ray cannot escape from the black hole.

Configure file: defl_of_light.

A detailed explanation of the configuration file can be found in appendix A.

It could also be interesting to find the initial position \(y\) where the light ray approaches the photon orbit asymptotically. Here, we have \(y \approx 3.9508265\). For that, however, it would be better to change the numerical integration from the standard Runge–Kutta fourth-order integrator without step size control to the Runge–Kutta–Fehlberg integrator with step size control and absolute error tolerance of \(\varepsilon_{abs} = 10^{-12}\). Then, the constraint equation for the light ray is fulfilled until the light ray reaches the horizon.

3.2. Einstein ring

In the previous example, we have seen that for some specific initial positions \(y\), the light ray orbits the black hole and returns to the observer. Due to the symmetry of the Schwarzschild
spacetime, this happens also for light rays which lie in a plane that is rotated around the connecting axis between the observer and the black hole. As a result, the observer will see himself as an Einstein ring around the black hole. However, there is not only one but an arbitrary number of Einstein rings.

One method to find the geodesics that return to the observer would be to solve the geodesic equations analytically; see e.g. Müller [4]. But this is extremely laborious even for the more adequate spherical coordinates. Another possibility, known from solving ordinary differential equations, is the shooting method which can be easily simulated using GeodesicViewer and varying the initial direction $\xi$.

**Exercise:** Start GeodesicViewer and select the Schwarzschild metric in isotropic coordinates (SchwarzschildIsotropic) in the ‘Metric/Integrator/Constants’ window. Set the position of an observer in the ‘Local Tetrad’ window to $(t = 0, x = 6, y = 6, z = 0)$. Find the initial directions $\xi$ of the light rays that orbit the black hole once, twice, or three times, cf figure 4, before returning to the observer.

**Result:** The initial directions $\xi$ with respect to the observer’s local reference frame, cf figure 2, read $\xi_1 = 195.668165^\circ$, $\xi_2 = 195.96490458^\circ$, and $\xi_3 = 195.965451625^\circ$.

**Configure file:** einstein_ring_1,einstein_ring_2,einstein_ring_3.

**Exercise:** The situation is as before. But now the observer sends out a flash of light and measures the time until the Einstein rings appear: $\tau_1 \approx 40.1480$, $\tau_2 \approx 69.2052$, $\tau_3 \approx 98.2203$. What is the relation between proper time and coordinate time? Switch to the 2D view and use the coordinate time ‘t’ as abscissa and ‘x’ as ordinate.

**Result:** From figure 5, we can read the light travel times $t_i$ for the light rays with initial directions $\xi$. The relation between the coordinate time $t_i$ and the proper time $\tau_i$ for a fixed observer position is constant.
Studying null and time-like geodesics in the classroom

Figure 5. Light travel times for the light rays of figure 4 in the 2D coordinate representation: $t_1 \approx 45.1758$, $t_2 \approx 77.8718$, $t_3 \approx 110.5205$.

Figure 6. Shapiro time delay. The solid line represents the real light ray, whereas the dashed line is the rectilinear approximation. Impact parameter: $y = R$. Position of the observer and the source: $x_{\text{obs}} = X$, $x_{\text{source}} = -X$.

Configure file: light_travel_time.

This example could also be formulated for given observer positions $\rho$ and corresponding light travel times $\tau(\rho)$ as measured by the observer. To prepare this exercise, the coordinate times $t$ for one orbit have to be determined in advance for several radial positions $\rho$. Then, by means of the relation $\tau/t = \sqrt{1 - r_s/r} = \sqrt{1 - 4\rho_s/\rho(1 + \rho_s/\rho)^2}$, which shall be found by the students, the proper times $\tau$ can be determined. Probably, this relation could be easily found in the standard spherical Schwarzschild coordinates.

3.3. Shapiro time delay

In [5], Rindler discusses the Shapiro time delay by means of a situation similar to the one shown in figure 6. A light ray emitted at $x_{\text{source}} = -X$ passes a spherical mass $M$, which is located at $(x = 0, y = 0)$, at $y = R$ and reaches the observer at $x_{\text{obs}} = X$. From the isotropic metric, equation (1), together with $ds = 0$ and $\rho = \sqrt{X^2 + R^2}$, he deduces the total coordinate time

$$\Delta t \approx 2X + r_s \ln \frac{4X^2}{R^2}, \quad (11)$$

where the logarithmic term is the Shapiro time delay.

Exercise: Start GeodesicViewer and select the Schwarzschild metric in isotropic coordinates. Find a geodesic that connects the observer, located at $x_{\text{obs}} = 200$, with a light source at position $x_{\text{source}} = -200$. Compare the total light travel time with the approximation by Rindler.
Result: The light ray that connects the observer and the light source in figure 6 has an initial angle $\xi \approx 173.857 \, 8332^\circ$. Rindler’s approximation, equation (11), yields $\Delta t \approx 412.0797$, whereas from GeodesicViewer we obtain $\Delta t \approx 414.579$.

Configure file: shapiro.

4. Periodic orbits of time-like geodesics in black hole spacetimes

The most simple periodic orbit of a time-like geodesic in the Schwarzschild spacetime is a circular orbit. The relation between the radius $r$ of the orbit and the corresponding velocity $\beta$ can be easily found within the original, spherically symmetric Schwarzschild coordinates. In isotropic coordinates, this relation reads

$$\beta^{-1} = \sqrt{2 \left( \frac{\rho}{4\rho_0} \left( 1 + \frac{\rho_0}{\rho} \right)^2 - 1 \right)},$$

(12)

which is valid only down to the last stable orbit, $\rho \geq \rho_{\text{lo}} = (5 + 2\sqrt{6})\rho_s$. However, besides these circular orbits, there are also more complex periodic orbits. Levin and Perez-Giz [6] give a whole taxonomy of periodic orbits. See appendix B on how to reproduce the orbits shown in their paper.

In the following exercise, we will consider periodic orbits for Kerr black holes. In Boyer–Lindquist coordinates, see e.g. Bardeen et al [7], the Kerr metric reads

$$ds^2 = -\left(1 - \frac{r_J}{\Sigma}\right)c^2 dt^2 - \frac{2r_Ja r \sin^2 \theta}{\Sigma} c \, dt \, d\phi + \frac{\Sigma}{\Delta} dr^2 + \Sigma \, d\theta^2 + \left( r^2 + a^2 + \frac{r_Ja^2 r \sin^2 \theta}{\Sigma} \right) \sin^2 \theta \, d\phi^2,$$

(13)

with $\Sigma = r^2 + a^2 \cos^2 \theta$, $\Delta = r^2 - r_J + a^2$, and $r_J = 2GM/c^2$. $M$ is the mass and $a$ is the angular momentum per unit mass of the black hole. As the observer’s local reference frame, we use the locally non-rotating tetrad

$$e_{(t)} = \sqrt{\frac{A}{\Sigma \Delta}} \left( \frac{1}{c} \partial_t + \omega \partial_\phi \right), \quad e_{(r)} = \sqrt{\frac{\Delta}{\Sigma}} \partial_r,$$

$$e_{(\theta)} = \frac{1}{\sqrt{\Sigma}} \partial_\theta, \quad e_{(\phi)} = \sqrt{\frac{\Sigma}{A \sin \theta}} \partial_\phi,$$

(14)

(15)

where $\omega = r_Ja r / A$ and $A = (r^2 + a^2) \Sigma + r_Ja^2 r \sin^2 \theta$.

Exercise: Select the Kerr metric in Boyer–Lindquist coordinates (KerrBL) and set the mass and angular momentum parameters to $M = 1$, $a = 1/2$. The observer is located at $(r = 6, \theta = \pi/2, \phi = 0)$. With respect to his locally non-rotating reference frame, cf ‘Natural local tetrad’ in the ‘Local Tetrad’ window, he starts a future directed time-like geodesic with initial velocity $\beta = 1/2$ and direction $\chi = 90^\circ$, $\xi = 67.649^\circ$; see figure 7. By varying the initial direction $\xi$, find periodic orbits of higher order. Instead of varying the initial direction, the initial velocity could also be changed.

Result: Periodic orbits of higher order follow from initial directions $\xi_2 \approx 82.95^\circ$, $\xi_3 \approx 72.6^\circ$, $\xi_4 \approx 70.58^\circ$, $\xi_5 \approx 75.1^\circ$, etc. For the fixed direction $\xi_1 = 67.65^\circ$, we can also change the initial velocity: $\beta_2 \approx 0.545$, $\beta_3 \approx 0.52006$, $\beta_5 \approx 0.528$.

Configure file: kerr_periodic.
5. Wormhole spacetime

The most simple non-trivial spacetime is that of a Morris–Thorne [8] wormhole whose metric, given in spherical coordinates, reads

\[ ds^2 = -c^2 dt^2 + dl^2 + \left( l_0^2 + l^2 \right) (d\theta^2 + \sin^2 \theta \ d\phi^2). \]  

(16)

Here, \( l_0 \) is the throat radius and \( l \) is the proper radial coordinate. The local reference frame of a static observer is given by

\[ e_{(0)} = \frac{1}{c} \partial_t, \quad e_{(1)} = \partial_l, \quad e_{(\theta)} = \frac{1}{\sqrt{l_0^2 + l^2}} \partial_\theta, \quad e_{(\phi)} = \frac{1}{\sqrt{l_0^2 + l^2} \ \sin \theta} \partial_\phi. \]  

(17)

To gain an impression of what the inner geometry of this wormhole spacetime looks like, we take advantage of the spherical symmetry and embed the \((t = \text{const}, \theta = \pi/2)\) hypersurface into the three-dimensional Euclidean space, cf for example [9]. The resulting embedding function reads

\[ z(r) = \pm l_0 \ln \left[ \frac{r}{l_0} + \sqrt{\left( \frac{r}{l_0} \right)^2 - 1} \right]. \]  

(18)

where the radial coordinates \( r \) and \( l \) are related via \( r^2 = l_0^2 + l^2 \). Figure 8 shows an embedding diagram for a wormhole with throat size \( b_0 = 1 \) and an observer at \((l = 10, \ \theta = \pi/2, \ \varphi = 0)\).

**Exercise:** Select the Morris–Thorne wormhole and set the throat size parameter \( b_0 = 1 \). The observer is located at \((l = 10, \ \theta = \pi/2, \ \varphi = 0)\) and uses the inward-oriented tetrad \( e_{(0)} = e_{(t)}, \quad e_{(1)} = -e_{(l)}, \quad e_{(2)} = e_{(\theta)}, \quad e_{(3)} = e_{(\phi)} \) as a local reference frame. A light ray with initial direction \( \chi = 90^\circ, \ \xi_0 = 0^\circ \) traverses the wormhole and hits the point \( P = (l = -10, \ \varphi = 0) \). Now, find the initial direction \( \xi_1 \) where the new light ray hits the point \( P \) again but now with \( \varphi = 2\pi \). Explain what an observer would see between \( \xi_0 \) and \( \xi_1 \).
**Figure 8.** Embedding diagram of a Morris–Thorne wormhole spacetime with $b_0 = 1$ and some exemplary null geodesics (black lines) with initial direction $k = e_{(t)} - \cos \xi e_{(\varphi)}$ starting at the observer’s position ($t = 10, \vartheta = \pi/2, \varphi = 0$).

**Figure 9.** Time-like periodic orbits in the extreme Reissner–Nordstrøm metric with the two black holes located at $z = \pm 1$. Left: the geodesic starts at $(x = y = 0, z = 3)$ with four-velocity $u = \gamma(e_{(t)} + \beta e_{(x)})$, where $\beta \approx 0.591943$ and $\gamma = 1/\sqrt{1 - \beta^2}$. Right: the geodesic starts at $(y = z = 0, x = 3)$ with four-velocity $u = \gamma(e_{(t)} + \beta \cos \xi e_{(x)} + \beta \sin \xi e_{(y)})$, where $\beta = 0.2$ and $\xi \approx 69.26$.

**Result:** A light ray with initial angle $\xi_1 \approx 5.64336^\circ$ travels around the wormhole throat before reaching the point $P$. Between $\xi_0$ and $\xi_1$ the observer would see the whole lower universe. Here, an interactive tool is indispensable to comprehend this fact.

**Configure file:** morristhorne.

Detailed discussions for the first-person visualizations of the Morris–Thorne wormhole can be found in Müller [10] or Ruder [11].

6. Multi black hole solution

Interesting general relativistic situations occur when several black holes are combined. These configurations will be inherently dynamical due to the mutual gravitational attraction between
the black holes. However, it is possible to construct static situations if one allows the black holes to carry an electric charge. Then the gravitational attraction can be compensated exactly by the electric repulsion. These solutions have been discovered by Majumdar [12] and Papapetrou [13]. They can be described as a collection of any number of extreme Reissner–Nordström black holes. We consider here the case of only two such black holes; see Chandrasekhar [14].

In Cartesian coordinates, the extreme Reissner–Nordström metric reads

$$ds^2 = -\frac{dt^2}{U^2} + U^2(dx^2 + dy^2 + dz^2),$$

(19)

where

$$U = 1 + \frac{M_1}{r_1} + \frac{M_2}{r_2}, \quad r_1 = \sqrt{x^2 + y^2 + (z - 1)^2}, \quad r_2 = \sqrt{x^2 + y^2 + (z + 1)^2}.$$  

Here, we use geometric units with $G = c = 1$. The two black holes are located at $x = y = 0, z = \pm 1$. As a local reference frame, we use

$$\mathbf{e}_t = U \partial_t, \quad \mathbf{e}_x = \frac{1}{U} \partial_x, \quad \mathbf{e}_y = \frac{1}{U} \partial_y, \quad \mathbf{e}_z = \frac{1}{U} \partial_z.$$  

(20)

For simplicity, we set $M_1 = M_2 = 1$.

**Exercise:** Select the extreme Reissner–Nordström metric (ExtremeReissnerNordstromDihole) and set the mass parameters of the two black holes to $M_1 = M_2 = 1$. Find time-like periodic orbits in the $xy$- and $xz$-planes. See figure 9 for two examples.

**Result:** Some exemplary time-like orbits are as follows: (1) $(x = 0, y = 0, z = 3), \quad u = \gamma (\mathbf{e}_t + \beta \mathbf{e}_x), \quad \beta \approx 0.896899$; (2) $(x = 0, y = 0, z = 3), \quad u = \gamma (\mathbf{e}_t + \beta \mathbf{e}_x), \quad \beta \approx 0.591943$; (3) $(x = 0, y = 0, z = 3), \quad u = \gamma (\mathbf{e}_t + \beta \mathbf{e}_x), \quad \beta \approx 0.451$; a light-like orbit is given by $(x = 0, y = 0, z \approx 1.720218), \quad k = \mathbf{e}_t + \mathbf{e}_x$.

**Configure file:** extrRNdihole1, extrRNdihole2, extrRNdihole3, extrRNdihole4, extrRNdihole5.

7. Summary and outlook

*GeodesicViewer* is a valuable tool for studying the behaviour of light-like and time-like geodesics in spacetimes whose metrics are provided analytically. While geodesics could also be visualized using standard software, a clear understanding of their behaviour can only be achieved by interactively manipulating the corresponding parameters.

In this paper, we have given a small number of possible applications formulated as exercises for students in the classroom. This can only hint at various other possibilities. The strength of *GeodesicViewer* lies in its visualization capabilities and to a large part in the available database of exact solutions. This allows the user to study the behaviour of geodesics in many different circumstances. The possibility of choosing the curve parameters in an interactive way means that one can make numerous parameter studies depending on the problem under consideration.

So far, *GeodesicViewer* can only handle one geodesic at once. This limitation will be overcome in a future version. We also plan to make *GeodesicViewer* scriptable to realize more complex demonstrations.

**Acknowledgments**

This work has been partly supported by the Marsden Fund of the Royal Society of New Zealand under contract number UOO0922.
Appendix A. Configuration file example for GeodesicViewer

As an example, we give here the configuration file for the ‘Deflection of light’ exercise of section 3.1 as written by GeodesicViewer. Although this file is a plain text file, we do not recommend modifying it by hand. Besides, not all of these parameters are crucial for this exercise.

GRAV_CONSTANT 1.00000000e+00
DIELECTRIC_PERM 1.00000000e+00
--------------------------------------------------------------------

Most of the parameters are self-explanatory. The time direction (TIME_DIR) can be either +1 or −1 depending on the geodesic being future- or past-directed. The method for solving the geodesic equation (GEOD_SOLVER_TYPE) is encoded by only a number, cf m4dMotionList.h of the Motion4D library. The absolute and relative error tolerances are given by the EPSILONS values. The numerical integration of the geodesic stops when the constraint equation with CONST_EPSILON is no longer fulfilled. For the local reference frame in this exercise, we use the default natural local tetrad. Hence, the TETRAD_TYPE is set to zero, the base vectors BASE_0 to BASE_3 build the identity matrix, and there is no boost transformation (the last value is the boost velocity). Since we use geometrical units, the speed of light and the gravitational constant are set to unity.

Appendix B. Periodic orbits by Levin and Perez-Giz

The periodic orbits in the Schwarzschild spacetime, shown in the paper by Levin and Perez-Giz [6], can be reproduced in isotropic coordinates in the following way. For a nearly arbitrary radial coordinate $r$, the initial velocity $\beta$ and the initial direction $\xi$ read
\[ \beta = \sqrt{1 - \frac{1 - r_s/r}{E^2}} \quad \xi = \arcsin \frac{L}{r \sqrt{E^2/(1 - r_s/r) - 1}}. \]  

(B.1)

The isotropic position is given by

\[ x = \frac{1}{2} (2r - r_s + 2\sqrt{r(r - r_s)}). \]  

(B.2)

For example, to reproduce the periodic orbit of figure 12 in their paper with parameters \( L = 3.9 \) and \( E = 0.987160 \), we set \( r = 10 \) and obtain \( \beta \approx 0.423147 \), \( \xi \approx 56.62467 \), and \( x \approx 8.972136 \).
