Hip Abductor Muscle Strength Deficit as a Risk Factor for Inversion Ankle Sprain in Male College Soccer Players

A Prospective Cohort Study

Investigation performed at The University of Tokyo, Tokyo, Japan

Background: Previous studies have attempted to determine whether certain risk factors can predict the occurrence of inversion ankle sprains in male collegiate soccer players. However, no consensus has been reached on the predictive risk factors of inversion ankle sprain in this population.

Purpose: To identify risk factors for inversion ankle sprains among male collegiate soccer players.

Study Design: Cohort study; Level of evidence, 2.

Methods: Included were 145 male collegiate soccer players in Japan who were assessed during a preseason medical checkup for potential risk factors of inversion ankle sprain. The preseason assessment included anthropometric measurements, joint laxity and flexibility, muscle flexibility, muscle strength, and balance ability, with a total of 33 variables. The participants were monitored during the 2019 season for inversion ankle sprains as diagnosed by physicians.

Results: A total of 31 inversion ankle sprains in 31 players (21.4%) occurred during the season. Only the measured isometric hip abductor strength was significantly lower in injured players as compared with uninjured players. Logistic regression analysis revealed measured hip abductor muscle strength deficit as a significant risk factor for inversion ankle sprain (odds ratio, 0.978 [95% CI, 0.976-0.999]; P = .05).

Conclusion: Hip abductor strength deficit was a risk factor for inversion ankle sprain in the study population. This finding could be useful for the prevention of inversion ankle sprains in male collegiate soccer players.

Keywords: inversion ankle sprain; hip abductor; risk factor; collegiate soccer player; injury prevention

Ankle sprains are among the most common musculoskeletal injuries observed in competitive athletes, and inversion (or lateral) ankle sprains are observed most frequently.9,18 Soccer is the most popular sport in the world and is characterized by rapid speed changes, pivoting, jumping, kicking, and cutting movements; therefore, ankle sprains represent one of the most common injuries in this sport.6,32,42 In addition, men aged 15 to 24 years have substantially higher ankle sprain rates than women.41 Surprisingly, ankle sprains accounted for approximately 30% to 40% of all injuries in young male soccer players.22 Additionally, long-term symptoms occur in up to 79% of players, and some players become frustrated with chronic ankle instability.1

Approximately 70% to 85% of ankle sprains are inversion-type (lateral-type) sprains.46 Therefore, from an injury-prevention standpoint, inversion ankle sprains in young male soccer players are of particular interest. To prevent inversion ankle sprains, we should recognize the risk factors in young male soccer players.

Several risk factors have been proposed to predict the occurrence of ankle injury. Previous injury history, especially with poor rehabilitation,1,8,10,15,21,30 has been proposed as the greatest contributor to future ankle injury. Extrinsic risk factors, such as exposure hours,34 weather, and competition level,33 have also been investigated as potential contributors. However, potential intrinsic risk factors, including age,2 lower limb range of motion,13 balance,14 body mass index,29 and muscular strength,4 are more clinically relevant, as they represent possible opportunities for intervention. Beynnon et al,6...
though, found little consensus in the literature with regard to whether such variables are always risk factors for ankle sprains. Additionally, previous studies on intrinsic risk factors of ankle sprain focused on deficits in muscle strength and flexibility and injury history independently and derived the risk factor from few possible factors. The most relevant risk factor for ankle sprain remains controversial, indicating the need for a prospective cohort study of multiple possible risk factors in the lower leg.

The aim of this study was to clarify risk factors of ankle inversion sprain prospectively in a relatively large, young male soccer population.

METHODS

A prospective cohort study was conducted on collegiate male soccer players in the 2019 season, with data on potential risk factors collected during a preseason medical assessment and participants monitored for injury during the season. This study was a part of a sports injury prevention project titled The Prospective Study of Predictors of Sports Injuries: UTokyo Sports Science Initiative. Players’ injury registration continued from the start of the study until the completion of the season. Medical assessment was performed before the start of the season for each player. This study was approved by the ethics committee of our institution, and consent was obtained from all participants.

A total of 145 male collegiate soccer players from 2 regional first-division collegiate soccer teams in Japan were enrolled in this study. None of the players were injured at the start of the study, and none reported any lower limb musculoskeletal injury in the prior 3 months. All participants received a preseason medical checkup and completed a questionnaire to identify their age, years of soccer experience, injury history, and medication. In this study, preseason data from 5 physical screening tests were used: anthropometric measurements, joint laxity and flexibility tests, muscle flexibility test, muscle strength test, and balance test.

Anthropometric Measurements

Each player’s body weight (BW) and height were measured at the preseason medical checkup, and body mass index was calculated for each player. Each body-composition parameter was measured using the InBody 270 (Biospace), which is a multifrequency impedance analyzer that can record each player’s lean soft tissue mass (skeletal muscle mass), body fat mass, and percentage body fat. Additionally, as a flat-foot index, the height of the navicular tubercle in each player’s foot was measured.

Joint Laxity and Flexibility

General Joint Laxity Testing

Each player underwent general joint laxity testing using the methods of the University of Tokyo as described by Watanabe et al.41 The test consisted of 7 conditions: thumb-to-forearm position, elbow hyperextension ≥15°, shoulder hyperrotation, hip hyper–external rotation ≥90° in the standing position, knee hyperextension ≥10°, ankle hyperdorsiflexion ≥45° of knee flexion, and trunk flexion with both palms touching the floor and knees fully extended. Shoulder hyperrotation was considered positive when participants could clasp their hands from the cranial and caudal sections of their back, and hip hyper–external rotation was considered positive when participants could maintain their hips at 90° of external rotation with both their lower legs in a neutral position. All tests except for trunk flexion and hip external rotation were performed bilaterally. A point value of 0.5 was given each time that a player surpassed the designated laxity measure at each side of the 5 joints tested (wrists, elbows, shoulders, knees, and ankles), and 1 point each was given for the trunk and hip, for a maximum possible score of 7.

Joint Flexibility

Joint-flexibility tests were performed for internal rotation of hip, ankle dorsiflexion, and knee extension based on previous studies.2,3 For internal rotation of hip, passive hip internal rotation angle in the prone position was measured. For ankle dorsiflexion, the weightbearing angle with knee flexion was measured. For knee extension, the knee hyper–extension angle was measured in a standing position with involvement of the quadriceps.

Muscle Flexibility

Muscle flexibility tests were performed bilaterally on the iliopsoas, quadriceps femoris, hamstrings, gastrocnemius, and soleus muscles (Figure 1).88 Flexibility of all muscles were measured by a skilled sports physician (Y.M.). Excellent intrarater reliability has been reported on all muscle

Muscle Strength Tests

Isometric Knee Extension and Flexion

Cybex Humac Norm (CSMi) was used for the measurement of knee flexion and extension muscle isometric strength. Before the measurement, the participant performed a 5-minute warm-up routine consisting of cycling on a stationary exercise bicycle. The order of which side was measured first was randomized, and each player was positioned on the dynamometer so that the hip was flexed to 90°, ensuring that the dynamometer and knee joint axes were aligned. Testing consisted of isometric contraction at knee flexion and extension at 70°, and the highest peak torque value was recorded. Strength measures were recorded as measured and normalized to BW.

Isometric Hip Abduction

The strength of the hip abductors was measured isometrically using a handheld dynamometer (μTAS F-1; Anima Industry). To allow for a standardized testing procedure, all participants lay supine with the hips in a neutral position beside the wall, both knees extended, and arms crossed over the chest. As the participants were instructed to abduct the leg as much as possible over 5 seconds, with 1 minute of rest between contractions, the peak force was retained for further analysis. The dynamometer was placed on the lateral epicondyle of the femur, and the distance between the lateral epicondyle and hip center was measured (Figure 2). Previous isometric hip abductor strength assessed with a handheld dynamometer has had good to excellent intra- and intertester reliability.27,37 The highest peak torque value was recorded. Strength measures were recorded as measured and normalized to BW.
Balance Tests

We measured double- and single-leg stance balance with a 1-m Footscan pressure plate with 8192 resistive sensors and a pixel resolution of 5.08 × 7.62 mm (RSscan International), with a sampling frequency of 250 Hz. The procedures used were based on methods previously described.19 The participant performed a 30-second trial of double-leg standing balance barefooted with arms crossed over the chest and eyes opened. After a 30-second interval, each participant then performed a 30-second trial of single-leg standing balance of each leg, similar to the double-leg test. The total distance of the center of pressure during the 30 seconds in both tests was measured as the balance parameter.26

Diagnosis of Inversion Ankle Sprain

Inversion ankle sprains were diagnosed and monitored by the team’s medical staff under the supervision of an orthopaedic team physician or directly by the team physician (K. Kawaguchi). For every injury, the date, type (eg, sprain), diagnosis (eg, inversion ankle sprain), and site (eg, left ankle) were documented, including the time of return to play and playing time lost. An injury was defined as a physical complaint that required restricted activity for at least 1 day and was considered only when it occurred during soccer practice or a game.23 Injury data were collected every 2 months from the medical staff in both teams.

Statistical Analysis

All statistical analyses were performed using SPSS Version 22.0 (IBM). Parameters except for those of the lower limb were compared between injured and uninjured players. Lower limb parameters were compared between the injured and uninjured contralateral limbs among the injured players as well as between the injured limb of injured players and the uninjured limbs of the uninjured players; each uninjured side was considered separately. The unpaired 2-tailed Student t test, Mann-Whitney U test, and Fisher exact test were used to assess continuous variables, nonparametric variables, and ordered variables, respectively. Of these examined factors, those showing a significant difference (P < .05) were further analyzed using multivariate logistic regression models to determine which could predict inversion ankle sprain. Two-tailed P values <.05 were deemed statistically significant.

RESULTS

Inversion ankle sprain occurred in a total of 31 ankles of 31 players (21.4%). No participants were lost to follow-up during the injury-registration period. Table 1 shows the characteristics of the players in the injured and uninjured groups, and Table 2 shows the comparison of injured and uninjured players in terms of anthropometric measurements, joint laxity tests, and balance test with double-leg stance. There were no statistically significant differences between the groups on any of the variables.

Table 3 shows the comparison between the injured and contralateral uninjured limbs of the injured players.

**RESULTS**

The most important finding in this study was that the hip abductor muscle strength deficit (measured value) was the significant risk factor of inversion ankle sprains in male collegiate soccer players.

Regarding abductor muscle strength, Powers et al. reported that reduced isometric hip abductor muscle strength was a predictor of ankle sprain in 185 male soccer players including adolescents and adults, and their conclusion was consistent with our result. However, they did not consider many possible risk factors, such as knee muscle strength, balance, and range of motion; as such, their results represent only a small aspect of a complex interaction among anthropometric measurements, muscle strength, balance, anatomic morphology, and other factors.

In contrast, our results were derived from many possible risk factors, including a complex interaction, and we revealed that reduced abductor muscle strength was the most important risk factor of inversion ankle sprain for young collegiate soccer players. In our study, post hoc analysis showed that our power was 0.61, which we thought was moderate to support our result. However, our results contrasted with those of McHugh et al., who reported that hip abduction strength had no influence on future lateral ankle sprain among 169 athletes. Their rate of ankle sprain in high school athletes was 5.9%, as calculated from in 1 season, and was relatively low. Therefore, it might be too low.
an injury rate to extract risk factors of ankle sprain, such as
deficiency of abductor muscle strength.

Given that the deficiency of abductor muscle strength
was the risk factor of ankle sprain, one possible mechanism
could be related to the role of the hip abductors in mainta-
ining pelvic and trunk stability during sports activities.
Ford et al\textsuperscript{41} reported that frontal pelvis obliquity was neg-
atively correlated with hip abductor strength during run-
ing in collegiate cross-country runners. Additionally, hip
abduction strength was shown to be correlated with pelvic
drop and hip adduction moment during single-leg squat,\textsuperscript{45}
and Cerny\textsuperscript{7} found that weakness in a stabilizing muscle,
such as the gluteus medius, may produce deviations in joint
motion and subsequent loss of stability. Hence, according to
these previous studies, hip abductor strength deficit could
lead to a more frontal pelvic and trunk tilt during soccer,
which could then induce insufficient control of the center of
gravity at a cutting or landing maneuver. With regard to
the relationship between the center of gravity and ankle
sprain, Wilkerson et al\textsuperscript{42} stated that, during changes in
balance, uncontrollable excessive lateral displacement of
the center of gravity results in increased lateral sway,
which causes the lateral border of the foot to act as a ful-
crum, with subsequent inversion of the ankle. The shifting
center of gravity could not be smoothly or sufficiently per-
formed in a cutting or landing leg, and the leg could be
unbalanced and likely injured. Therefore, inversion ankle
sprain is likely to occur in soccer players with abductor
strength deficit.

As another possible mechanism for abductor muscle
strength deficit as the risk factor of ankle sprain, foot place-
ment error could not be corrected because of it.\textsuperscript{12} Inversion
ankle sprains seem to be related to either unanticipated
foot placement on a sloped surface or inappropriate posi-
tioning of the foot in space before contact with a surface.\textsuperscript{36}
MacKinnon and Winter\textsuperscript{28} reported that errors in foot place-
ment are corrected at the hip joint or subtalar joint, which
work in synergy, and large errors in foot placement are
corrected at the hip. Interactions between the supporting
foot and hip musculature permit various strategies to be
used to maintain balance; in particular, control of pelvic
motion by the abductor strength is critical to maintaining
total body balance. Additionally, these interactions could be
the cause of functional ankle instability without mechanici-
analke instability. Tropp et al\textsuperscript{40} found that the ability to
maintain postural stability was reduced with functional
ankle instability but was not affected by mechanical ankle
instability. Therefore, the hip abductor muscle strength
deficit could negatively cause an unexpected foot placement
situation in a soccer game, and it could be one of the causes
of ankle functional instability.

Regarding previous speculation about ankle sprain and
center of gravity, postural stability was considered related
to an ankle sprain. Previous studies revealed a significant
correlation between poor static postural control and inver-
sion ankle sprain.\textsuperscript{14,44} Additionally, Powers et al\textsuperscript{30}
demonstrated a relationship between ankle sprain and hip
abductors in terms of postural stability. Persons with hip
abductor strength deficit showed decreased medial-lateral
postural stability, increased activation, and earlier onset of
the ankle evertors in an effort to prevent excessive ankle
inversion.\textsuperscript{24,25} Thus, abductor hip muscle strength deficit
could reduce postural stability. However, in this study, we
could not find any difference between the ankle sprain limb
and the uninjured limb in postural balance, which was
based on the displacement of the center of pressure during
the 30-second single-leg stance. This possibly occurs
because this task was relatively easy for athletes and may
not have been sufficiently discriminative in this population.
Additionally, this task was popularly used to assess pos-
tural stability in nonathletes.\textsuperscript{2} Therefore, it is necessary
to evaluate postural stability in athletes under less stable
conditions, such as a single stance blindfolded or single
stance with a balance board.\textsuperscript{16}

Previous studies reported that a history of ankle sprain
was one of the obvious risk factors of ankle inversion
sprain,\textsuperscript{8,10} because previous injury could alter the lower
limb kinetic chain for long periods after symptom dissipa-
tion, thereby increasing future injury risk.\textsuperscript{31} However, in
the present study, 48.3\% of injured limbs and 35.5\% of uninjured limbs had a history of ankle sprain, but no sig-
nificant difference was found. This may be due to a rela-
tively young sample population that is yet to incur any
significant injury,\textsuperscript{8,21} or it could be attributed to the level
of competition\textsuperscript{8,17,39} or play conditions.\textsuperscript{47} Although chronic
ankle instability could be a risk factor, this study did not
include mechanical or functional ankle instability evalua-
tion after ankle sprain. Therefore, further investigation
with a functional or mechanical evaluation is necessary.

This study has several limitations. First, it focused on
inversion ankle sprains in male collegiate soccer players
at a high competition level. Thus, our findings may not be
applicable to other sports or female athletes. Moreover, the
International Olympic Committee online meeting in 2019
suggested defining an injury as any condition that affects
an athlete’s normal state of full health, regardless of its
consequences on his or her sports participation or perfor-
ance or whether the athlete sought medical attention;
however, our study defines an injury as a physical com-
plaint that requires restricted activity for at least 1 day.
Therefore, our findings may not be applicable to minor
ankle injuries without resting sports activity. Second, this
study followed a relatively large cohort of collegiate soccer
players; nevertheless, 200 injury cases might be needed to
detect small to moderate associations in a prospective
cohort study.\textsuperscript{3} However, our prospective study of predictors
for sports injuries including ankle sprains is ongoing;
accordingly, we could reveal other weak to moderate risk
factors of ankle sprain in the future with more players and
injuries. Third, we collected the incidence of ankle sprain
for 1 year, and further investigation might reveal risk fac-
tors other than abductor muscle strength. Fourth, we
assessed only knee and hip muscle isometric strength, such
as knee extension, knee flexion, and hip abductor muscle
strength, and did not evaluate muscle strength around the
ankle. Thus, regarding whether other muscle strength
could be a risk factor, a meta-analysis showed that
decreased slow eccentric ankle inversion strength and
increased fast concentric plantar flexion strength signifi-
cantly correlated with lateral ankle sprain.\textsuperscript{20} We are now
prospectively assessing toe-grasping strength as a new strength factor around the foot and can reveal the results in the near future. Additionally, Baumhauer et al demonstrated that players with a muscle strength imbalance, as measured by an elevated eversion-to-inversion ratio, exhibited a higher incidence of inversion ankle sprains and that ankles with greater plantar flexion strength and a smaller dorsiflexion-to-plantar flexion ratio had a higher incidence of inversion ankle sprains. Therefore, abduction-to-adduction ratio could be worth investigating in future studies. Fifth, despite the dynamic balance needed for complex maneuvers in soccer, we evaluated only static isometric maneuvers in soccer, we evaluated only static isometric muscle strength and static balance. As such, dynamic muscle strength and dynamic balance ability are expected to be evaluated in future study. Additionally, functional and mechanical ankle instability was not included in this study and should be evaluated in future work. Sixth, we did not distinguish contact injury or noncontact injury. Finally, as this is an analysis of limited teams, the results may be influenced by the specific background of each team. It is thus not clear whether the results of this study are applicable to soccer players in general.

CONCLUSION

Hip abductor muscle strength deficit was an important risk factor for inversion ankle sprain in the study population. This finding could be useful for the prevention of inversion ankle sprain in male collegiate soccer players.

ACKNOWLEDGMENT

The authors gratefully acknowledge the cooperation of physicians, physical therapists, and athletic trainers as volunteer staff in our prospective study of predictors for sports injuries.
