doi:10.1111/febs.14458

The berberine bridge enzyme from the California poppy *Eschscholzia californica* (EcBBE) catalyzes the oxidative cyclization of (S)-reticuline to (S)-scoulerine, that is, the formation of the berberine bridge in the biosynthesis of benzylisoquinoline alkaloids. Interestingly, a large number of BBE-like genes have been identified in plants that lack alkaloid biosynthesis. This finding raised the question of the primordial role of BBE in the plant kingdom, which prompted us to investigate the closest relative of EcBBE in *Physcomitrella patens* (PpBBE1), the most basal plant harboring a BBE-like gene. Here, we report the biochemical, structural, and *in vivo* characterization of PpBBE1. Our studies revealed that PpBBE1 is structurally and biochemically very similar to EcBBE. In contrast to EcBBE, we found that PpBBE1 catalyzes the oxidation of the disaccharide cellobiose to the corresponding lactone, that is, PpBBE1 is a cellobiose oxidase. The enzymatic reaction mechanism was characterized by a structure-guided mutagenesis approach that enabled us to assign a catalytic role to amino acid residues in the active site of PpBBE1. *In vivo* experiments revealed the highest level of PpBBE1 expression in chloronema, the earliest stage of the plant’s life cycle, where carbon metabolism is strongly upregulated. It was also shown that the enzyme is secreted to the extracellular space, where it may be involved in later steps of cellulose degradation, thereby allowing the moss to make use of cellulose for energy production. Overall, our results suggest that the primordial role of BBE-like enzymes in plants revolved around primary metabolic reactions in carbohydrate utilization.

**Database**

Structural data are available in the PDB under the accession numbers 6EO4 and 6EO5.

**Introduction**

The berberine bridge enzyme (BBE)-like protein family is a large enzyme family found in bacteria, fungi, and plants, named after its best characterized member, the BBE from *Eschscholzia californica* (EcBBE, EC 1.21.3.3). In Californian poppy (*E. californica*), BBE participates in the biosynthesis of benzylisoquinoline alkaloids, where it catalyzes the oxidative formation of the berberine bridge resulting in the conversion of

**Abbreviations**

BBE, berberine bridge enzyme; GOOX, glucooligosaccharide oxidase; PpBBE1, berberine bridge enzyme homolog from *Physcomitrella patens* (gene #1); THCA, Δ⁹-tetrahydrocannabinolic acid.
(S)-reticuline to (S)-scoulerine [1]. Whole-genome sequencing efforts have revealed the occurrence of many BBE-like genes in virtually all plants even those that lack alkaloid biosynthesis [2]. In the model plant Arabidopsis thaliana, for example, 27 genes were identified to encode BBE-like enzymes, with an even higher number found in Citrus clementina (41 genes), Glycine max (43 genes), and Populus trichocarpa (65 genes). Despite the ubiquitous and abundant presence of BBE-like proteins in the plant kingdom, the biochemical and physiological function of the enzymes remain largely unknown. Based on multiple sequence alignments, the 27 BBE homologs of A. thaliana were classified into seven subfamilies [3]. Recent studies have successfully assigned a function to two of these subfamilies, demonstrating oxidation of indole cyano-hydrins and monoglucosinolates to the corresponding keto and aldehyde products, respectively [3,4]. Besides, earlier reports on enzymes involved in plant defense have implicated BBE-like proteins in the oxidation of monosaccharides derived from glucose as well as from galactose [5]. A similar activity was also assigned to the pollen allergen Phl p 4 [6] and to nectarin 5, a BBE-like protein from ornamental tobacco [7].

Unlike most other plants, the genome of the moss Physcomitrella patens harbors only two genes that can be assigned to the BBE-like family [8]. Gene #1 (Pp3c12_2640V3.1) shares the highest sequence identity with fungal carbohydrate oxidases (ca. 30% identity on the amino acid sequence level) and is closely related to EcBBE and other plant enzymes from the BBE-like family (25–28% identity on the amino acid sequence level). In contrast, gene #2 (Pp3c2_12420V3.1) has a much lower similarity to EcBBE (<20% sequence identity) and is more closely related to the ecddyterroid-22-oxidase from Metarhizium rileyi (29.3%; Uniprot: I0J0L0).

Because of the role of P. patens as a paradigm for the conquest of land by plants [9], we reasoned that unraveling the function of the moss BBE-like protein would provide insight into the evolutionary origin of this ubiquitous multigene family in plants. Toward this goal, we have produced the BBE homolog, termed PpBBE1 and encoded by gene #1 (Pp3c12_2640V3.1), in the methylotrophic yeast Komagataella phaffii and subsequently characterized the purified enzyme biochemically and structurally. In addition, expression and secretion of the wild-type protein as well as the phenotypical characteristics of a knockout strain were studied in order to reveal the in vivo function of the enzyme. Here, we report that PpBBE1 is an efficient cellobiose oxidase that is very similar to fungal BBE-like oxidases, such as gluco-oligosaccharide oxidase (GGOX), in terms of the active site composition as well as the enzymatic reaction mechanism. Our in vitro findings are further supported by the data obtained from in vivo experiments since the highest level of expression could be detected in chloronema, an early stage of the plant’s life cycle, where carbohydrate metabolism is strongly upregulated [10,11]. Thus, our results suggest that the diversity of enzymatic reactions found in the BBE-like protein family in the plant kingdom originated from this ‘primordial’ carbohydrate oxidase.

Results

Gene organization, expression, and secretion of Physcomitrella patens BBEs

According to the latest release of the genome V3.3 available on cosmoss.org, PpBBE1 is located on chromosome 12 and represented by the gene model Pp3c12_2640V3.1 encoding a protein of 501 amino acids. The full-length gene comprises 3243 bp, of which 2808 bp belong to the coding sequence. The latter consists of a 5'-UTR of 498 bp, a transcript of 1506 bp and a 3'-UTR of 804 bp, with the transcript being formed by three exons (99, 256, and 1151 bp for exon 1, 2, and 3, respectively) and two introns. PpBBE3 (note that PpBBE2 was identified as a pseudogene) is located on chromosome 2 and represented by Pp3c2_12420V3.1, consisting of two exons and an intron, encoding a protein of 586 amino acids (Fig. 1A).

The expression of PpBBE1 throughout the whole life cycle and upon different growth conditions was analyzed in silico using publicly available transcriptomic data based on microarray experiments [12,13]. PpBBE1 is highly expressed in protoplasts and chloronema cells, which both harbor large and numerous chloroplasts. Analysis of the caulonema, the fast-growing cell type of protonema from which buds arise and which is characterized by fewer chloroplasts and slimmer cells with oblique cell walls, in contrast, did not reveal any expression. In the gametophore, expression of PpBBE1 was restricted to the green parts, whereas in rhizoids, no expression was detected. During sporophyte development, PpBBE1 expression was only detectable in unfertilized archegonia, the female sexual organs, and the mature spore capsule while PpBBE3 expression was restricted to the late stages of sporophyte development ([12]; Fig. 1B). On dedifferentiation of leaves to chloronema as well as after incubation in darkness, PpBBE1 expression was upregulated [13].

PpBBE1 is about 54 kDa and harbors a predicted N-terminal signal peptide (1–30) according to SignalP.
[14] as well as an internal FAD-binding domain (78–216, PF01565) and a C-terminal BBE domain (457–499, PF08031) according to the PFAM protein domain annotation [15]. Furthermore, the \( Pp\) BBE1 was identified in the supernatant of \( P.\ patens \) liquid cultures by mass spectrometry whereas \( Pp\) BBE3 was not detected.

**Production and purification of PpBBE1 and basic characterization**

The gene of the \( P.\ patens \) BBE-like protein encoded by locus \( Pp3c12\_2640V3.1 \) (gene #1) was expressed in the methylotrophic yeast \( Komagataella paffii \) as described in Experimental procedures. The protein (molecular mass 54 kDa) was secreted into the culture medium and purified by Ni-NTA affinity chromatography using the C-terminal octahistidine tag. Typical yields of pure protein varied between 5 and 7 mg L\(^{-1}\) of culture. The UV-Vis absorption spectrum of purified \( Pp\) BBE1 exhibited two peaks at 375 and 443 nm indicating the presence of a flavin chromophore (Fig. 2, black line). Denaturation of the protein resulted in a single peak at 440 nm (Fig. 2, red line). Similar spectral changes were reported for other members of the BBE family and reflect the bicovalent linkage of the isoaflaxazine ring via the C6- and 8\( a\)-position to a cysteine and histidine residue, respectively [2,16–18]. As both residues are conserved in the sequence of
PpBBE1 (H111 and C172), the observed spectral properties are in accordance with the formation of both covalent linkages. To further substantiate the presence of two covalent linkages, the protein was photoreduced under anoxic conditions. As shown in Fig. 3, reduction initially yielded the anionic flavin semiquinone, which was then further reduced to the flavin hydroquinone (Fig. 3A,B). Reoxidation of the fully reduced sample yielded absorption characteristics typical for a 6-thioflavin with a sharp peak at 425 nm and a broad absorption centered at 750 nm (Fig. 3B,C). The underlying cleavage of the carbon–sulfur bond in the covalently linked cysteine residue was previously observed for EcBBE [16] and appears to occur in all bicovalently linked flavins found in the BBE family. Yet, another hallmark of bicovalently linked flavins is their unusually high redox potential, which is typically more positive than +100 mV, for example, +132 ± 4 mV for EcBBE [17]. Thus, we also determined the redox potential for PpBBE1 using the dye equilibration method [19]. As shown in Fig. 4, the reporting dye and the flavin were reduced synchronously allowing to plot the log of the ratio of oxidized vs reduced dye against the log of the ratio of oxidized vs reduced enzyme-linked FAD (Fig. 4A,B). From this Nernst plot, a redox potential of +121 ± 1 mV was obtained, which is comparable with other BBE-like enzymes [2,17,20].

Identification of substrates

Based on the fact that the majority of BBE-like enzymes in bacteria and fungi oxidize alcohol groups of a variety of complex saccharide structures, an initial screening for enzymatic activity focused on mono-, di-, and polysaccharides (for a complete list of compounds, see Experimental procedures). This promptly revealed that PpBBE1 oxidizes the two 1,4-β-linked disaccharides cellobiose and lactose. A more detailed kinetic analysis by steady-state kinetics yielded a higher apparent $k_{cat}$ and lower apparent $K_M$ for cellobiose, that is, 48 s$^{-1}$ vs 28 s$^{-1}$ and 0.6 mM vs 4.2 mM, respectively, indicating that the catalytic efficiency with cellobiose is 10 times higher than with lactose ($k_{cat}/K_M = 8 \times 10^4$ M$^{-1}$s$^{-1}$ and $7 \times 10^3$ M$^{-1}$s$^{-1}$ for cellobiose and lactose, respectively; Fig. 5). In order to identify the oxidation product, cellobiose was used in a scale-up experiment to obtain sufficient amounts of product, which was subsequently analyzed by NMR spectroscopy (see Experimental procedures for details). The NMR spectra clearly demonstrate the formation of cellobionolactone, that is, the free anomeric center of cellobiose is oxidized to the corresponding lactone,

Fig. 3. Photoreduction in PpBBE1 under anoxic conditions. (A) UV-Vis absorption spectra of PpBBE1, diluted to a final concentration of about 15 μM with 50 mM HEPES pH 7, were recorded during anaerobic photoreduction. The strong increase in absorption at 371 nm within the first minutes indicates the formation of an anionic flavin semiquinone [compare start spectrum (black) with spectrum recorded after 4 min (green line)], which was subsequently reduced to the flavin hydroquinone (brown line); (B) Reoxidation of PpBBE1 following photoreduction. The broad peak observed in the spectrum after full reoxidation (blue line) between 600 and 900 nm indicates the formation of 6-thio-FAD; (C) Comparison of the UV-Vis absorption spectra of native (black), fully reduced (blue), and fully reoxidized (red) PpBBE1.
which spontaneously hydrolyses to the ring-open acid form (see Fig. S1). Finally, we determined the pH-dependence of the reaction under steady-state conditions. As shown in Fig. 6, the activity of \( PpBBE1 \) reached a maximum at pH 5.8 (black squares).

**Presteady-state experiments with cellobiose**

To further evaluate the reductive and oxidative half-reaction of the enzyme, we conducted presteady-state experiments in the stopped-flow apparatus (see Experimental procedures). First, the rate of reduction in \( PpBBE1 \) was measured as a function of cellobiose concentration. The rate of reduction increased linearly with the cellobiose concentration and saturation was not observed up to 1 mM. At higher concentrations, the observed rate constants could not be extracted reliably due to the dead time restrictions of the instrument. Due to this limitation, we were unable to determine or fit a limiting rate of reduction and a dissociation constant for cellobiose. Therefore, we have used the determined bimolecular rate constant of Fig. 4.

**Fig. 4.** Determination of the redox potential of \( PpBBE1 \) (in 50 mM HEPES pH 7). (A) The UV-Vis absorption spectra recorded during the reduction reaction. (B) Nernst plot obtained from the experimental data, that is, \( \log(\text{PpBBE1}_{\text{red}}/\text{PpBBE1}_{\text{ox}}) \) vs the \( \log(\text{dye}_{\text{ox}}/\text{dye}_{\text{red}}) \). The slope of near unity (0.96) is in keeping with a two-electron transfer process for both enzyme and the dye; the intercept was used to calculate the redox potential of \( PpBBE1 \) (+121 ± 1 mV from three determinations).

**Fig. 5.** Steady-state kinetics performed with \( PpBBE1 \) using cellobiose (A) and lactose (B) as substrates. Reaction rates were determined at pH 6, near the pH-optimum of \( PpBBE1 \) wild-type, keeping the enzyme concentration constant (10 nM) and varying the substrate concentration (cellobiose: 50–1500 \( \mu \)M; lactose: 250–8000 \( \mu \)M). From these data, it can be concluded that \( PpBBE1 \) shows an about 10-fold higher catalytic efficiency with cellobiose than with lactose (apparent \( k_{\text{cat}}/K_M = 8 \times 10^3 \pm 7 \times 10^2 \text{ and } 7 \times 10^3 \pm 1 \times 10^3 \text{ M}^{-1}\text{s}^{-1} \) from three determinations, respectively; the standard deviations are displayed as error bars).
In order to gain further insights into the structure X-ray crystallographic structure of times slower than the rate of reduction.

The FEBS Journal 1928

Fig. 6. Comparison of the pH-profile of wild-type PpBBE1 (black) and the D396A variant (red). Reaction rates were determined in the pH-range from 4 to 8, using cellobiose (500 μM) as substrate and DCPIP (100 μM) as final electron acceptor. All reactions were started upon addition of the enzyme (wild-type: 10 nM; D396A: 200 nM) and the decrease in absorption at 600 nm was monitored for 120 s. The wild-type enzyme showed highest activity at pH 5.8, whereas the pH-optimum of the variant was shifted by more than one pH-unit to pH ~7.2 (turnover rates at the different pH-values were determined in triplicates; the standard deviations are displayed as error bars).

1.7 × 10^5 M^{-1}\cdot s^{-1} for further comparison and discussion. The rate of reoxidation of the reduced flavin by dioxygen was determined at a final oxygen concentration of 140 μM to 0.5 × 10^5 M^{-1}\cdot s^{-1} and is thus ca. 3 times slower than the rate of reduction.

X-ray crystallographic structure of PpBBE1

In order to gain further insights into the structure–function relationships in the active site of PpBBE1 and to develop a more detailed enzymatic reaction mechanism, we solved the three-dimensional structure by X-ray crystallography. Hanging drop vapor-diffusion crystallization was used to obtain light yellow, tetragonal bipyramidal crystals of wild-type protein as well as a protein variant (D396N) that was generated in the course of our site-directed mutagenesis study (see site-directed mutagenesis of putative active site residues). Crystals of the D396N variant generally diffracted to higher resolution and data generated from these crystals was, therefore, used for phasing of the structure. Including data up to a resolution of 2.6 Å, the structure was solved by molecular replacement using a homology model based on \textit{Ar}BBE-like 15 (PDB: 4UD8; [3]) as template, confirming a protein fold, that had previously been shown for BBE-like enzymes (Fig. 7) [2]. An identical structure was then confirmed for the wild-type data refined to 2.9 Å after phasing with the initial model of the variant. PpBBE1 crystallized as a loose dimer in the asymmetric unit with a dimerization interface of no biological significance according to PISA analysis [21]. In line with gel filtration experiments, PpBBE1 is, therefore, expected to be functional as a monomer. Individual protomers also showed no substantial structural differences with a root-mean-square deviation of 0.15 Å for 404 aligned backbone Cα residues. A closer inspection of the active site revealed a relatively large active site with clear interpretable electron density of all active site residues. In addition, continuous electron density between the 8α- and C6-positions of the flavin cofactor and residues H111 and C172, respectively, confirmed the bicovalent linkage of the flavin cofactor. Both wild-type and the D396N structure featured a pronounced density at the expected site of substrate binding that could not be interpreted at the current resolution limits. Interestingly, the density projects toward the C4a atom of the flavin cofactor and might thereby explain the unexpectedly weak yellow coloration of the crystals. Further studies are needed to identify the source of this copurified ligand species.

The closer inspection of the active site revealed six residues with a potential role in substrate binding and activation (Fig. 8). Among these residues, two are likely to be required for substrate activation. D396 forms a hydrogen bond with Y461 and thereby may assist in the deprotonation of the tyrosine residue, which, in turn, could serve as catalytic base. Q424, which is in close vicinity to Y461 and D396, might also contribute to the activation of Y461, but could also play a role in substrate coordination or activation. The role of W186 and S422 is less obvious. Being able to interact with peptide backbone of L397 and the side chain of Y398, respectively, these two residues might also contribute to the activation of Y461, but could be responsible for the correct positioning of D396 relative to Y461, but from the crystal structure, their importance is difficult to predict.

Site-directed mutagenesis of putative active site residues

In order to obtain more detailed information on the role of various active site residues, we initiated a site-directed mutagenesis program. Thus, all six amino acid residues found in close vicinity of the flavin cofactor were replaced, that is, tyrosine 113 and 461 to phenylalanine (Y113F and Y461F), aspartic acid 396 to alanine and asparagine (D396A and D396N), glutamine 424 to alanine (Q424A), tryptophan 186 to phenylalanine (W186F), and serine 422 to alanine (S422A). In addition, the residue held responsible for controlling the
oxygen reactivity on the si-side of the isoalloxazine ring, that is, valine 175, was replaced by leucine (V175L; Fig. 8). As shown in the summary of kinetic parameters in Table 1, the replacement of Y461, D396, W186, S422, and Q424 significantly affected the catalytic rates whereas replacement of Y113 caused only marginal changes compared to the wild-type enzyme. These results further support the hypothesis that D396 acts as an active site base and therefore determines the pH-profile of the enzyme. This concept is also in agreement with the observation that replacement of D396 by an alanine resulted in a substantial shift of the pH-optimum from ~5.8 to ~7.2 (Fig. 6, red spheres).

Previously, we established that the oxygen reactivity of the reduced flavin in the BBE-like enzyme family is controlled by a single ‘gate keeper’ residue on the si-side of the isoalloxazine ring. In the case of PpBBE1, V175 is found in the pertinent ‘gate keeper’ position, and thus, the reduced enzyme is expected to rapidly react with dioxygen, as confirmed by the high rate of reoxidation, that is, 0.5 × 10⁵ M⁻¹ s⁻¹. In accordance with our ‘gate keeper’ model, replacement of this valine by leucine diminished the rate of reoxidation to ~25 M⁻¹ s⁻¹, thus basically suppressing the reaction of the reduced flavin with dioxygen as previously found for other members of this enzyme family [3,20,22].

**Molecular docking and molecular dynamics simulations**

As the substantial decrease in enzymatic activity of some variants could not be fully explained based on the crystal structure alone, molecular docking and subsequent molecular dynamics simulations with PpBBE1 and cellulose were performed. The docking experiment resulted in a reasonable binding of cellulose to the active site of PpBBE1, though some distances between the ligand and interacting residues were not in a favorable range. Therefore, two independent molecular dynamics simulations based on the previously obtained docking results were conducted (Fig. 8A).

The resulting average structures demonstrated a high flexibility of Y461, as the distance between D396 and the tyrosine as well as between the tyrosine and the anomic hydroxyl group of cellulose strongly differed in the two simulations (Fig. 8B,C). In one simulation, Y461 is in hydrogen-bonding distance with D396 by an alanine resulted in a substantial shift of the pH-optimum from ~5.8 to ~7.2 (Fig. 6, red spheres).

Previously, we established that the oxygen reactivity of the reduced flavin in the BBE-like enzyme family is controlled by a single ‘gate keeper’ residue on the si-side of the isoalloxazine ring. In the case of PpBBE1, V175 is found in the pertinent ‘gate keeper’ position, and thus, the reduced enzyme is expected to rapidly react with dioxygen, as confirmed by the high rate of reoxidation, that is, 0.5 × 10⁵ M⁻¹ s⁻¹. In accordance with our ‘gate keeper’ model, replacement of this valine by leucine diminished the rate of reoxidation to ~25 M⁻¹ s⁻¹, thus basically suppressing the reaction of the reduced flavin with dioxygen as previously found for other members of this enzyme family [3,20,22].

**Generation and analysis of BBE-deficient moss mutants**

To analyze the function of PpBBE1 in vivo, we generated moss AΔpBBE1 knockout mutants deleting the

**Fig. 7.** Overall crystal structure (A) and close-up view of the active site (B) of PpBBE1. (A) Structure of the PpBBE1 as determined by X-ray crystallography shown in cartoon representation, with the subdomain involved in substrate highlighted in green and the FAD-binding domain in purple, blue, and red. The FAD cofactor (yellow) and the two amino acids responsible for its bicovalent attachment are shown as sticks (H111, purple and C172, blue). (B) Close-up of the active site of PpBBE1. The function of the amino acid residues shown were probed by site-directed mutagenesis (see text for details).
coding sequence almost completely. A 3.6 kb long fragment was amplified from genomic DNA and the central part of this fragment comprising nearly the whole-coding sequence leaving only 38 bp of exons 1 and 37 bp of exon 3 was replaced by the nptII selection cassette (Fig. 9A). After poly(ethylene glycol)-mediated protoplast transformation (done in six independent approaches), antibiotic selection, and regeneration [23], 915 surviving colonies were picked. In an initial screening of 28 colonies by leaflet PCR [24], 12 putative ΔPpBBE1 lines were identified and validated by RT-PCR (Fig. 9B). Flow cytometry analysis [25] confirmed that these lines were haploid. Subsequently, the copy number of the targeting construct was analyzed with a qPCR-based method on genomic DNA (Fig. 9C; [26]). For all further experiments, three ΔPpBBE1 single integration lines (#80, #83 and #100) were used.

Growth and morphology of ΔPpBBE1 plants were unchanged compared to WT throughout the whole life cycle from protoplast regeneration to sporophyte development. Also, upon salt stress, neither gametophores on solid plates nor protonema in liquid culture showed a phenotype differing from WT. In order to study the effect of ΔPpBBE1 on the degradation of the carbohydrate cellobiose, the plants were grown on media supplemented with either 0.5% cellobiose or 0.5% glucose, which is known to delay differentiation by prolongation of juvenile stages [27] and also promotes growth of Physcomitrella cultures in low light conditions [28]. Growth and development of ΔPpBBE1 lines were studied with and without supplementation of carbohydrates in standard growth conditions (16 h light, 8 h darkness) or darkness. Therefore, protonema cultures were grown in liquid medium (Fig. 10A) and protonema spot inocula (Fig. 11A) or single gametophores (Fig. 11B) were used as starting material on solid medium. In all conditions, no difference between ΔPpBBE1 and WT was detected regarding growth rate and development. The addition of cellobiose to

Fig. 8. Results from molecular dynamic simulations performed after docking of cellobiose to the crystal structure of PpBBE1. (A) Cellobiose-binding mode, including hydrogen-bonding interactions predicted by MD-simulations (for color coding, see Fig. 6; cellobiose is shown as orange sticks). (B) Distances between possible interaction partners as predicted in two independent MD-simulation runs (see black dashed lines in panel A). (C) Time-dependent change in the distance between the two catalytic residues Y461 and D396 monitored for 12.5 ns.
cultures grown in the dark led to an intermediate phenotype between the control without a carbohydrate source and media supplemented with glucose, but again no significant difference between the WT and the knockout strain could be observed.

In addition to the phenotypical analysis, qualitative and quantitative analysis of the glucose and cellobiose content in the supernatant of the liquid cultures was performed. After 3 weeks of incubation, the presence of reducing sugars was assayed with the Benedict’s test, before conducting a quantitative analysis using the 3,5-dinitrosalicylic acid (DNS) assay (Fig. 10B) and glucose test strips (for details the Experimental procedures). As before, no differences between ΔPpBBE1 and WT cultures were observed. Similarly, cultures that were grown on plates for 4–6 weeks were analyzed in terms of the carbohydrate content in the solid media using congo red staining. Again, this analysis did not reveal any difference between ΔPpBBE1 and WT.

**Discussion**

The successful expression of gene #1 (Pp3c12_2640V3.1) in *K. paffii* led to the production of suitable amounts of PpBBE1 and enabled us to carry out the
biochemical and structural characterization of the enzyme. In the course of our studies, we identified the disaccharide cellobiose as the best substrate, which is oxidized at the free anomeric center to the corresponding cellobionolactone and spontaneously hydrolyses to cellobionate. The rate of cellobiose oxidation is very fast and exceeds the rate observed for many other flavin-dependent oxidases [29–32]. In fact, the observed bimolecular rate constant already at rather low substrate concentrations is greater than the rate of reoxidation of the reduced flavin by dioxygen, which was also observed for other enzymes belonging to the BBE-like protein family. Thus, *PpBBE1* clearly harbors a very efficient active site for the oxidation of cellobiose. In order to understand the catalytic contributions of the amino acids in the active site, we have generated a set of seven variants and determined the relevant kinetic parameters (Table 1). In conjunction with the crystal structure of *PpBBE1*, we are now in a position to propose an enzymatic reaction mechanism for the oxidation of cellobiose. As shown in Scheme 1, we propose that the side chain carboxylate group of D396 deprotonates the neighboring side chain of Y461, which in turn abstracts a proton from the

**Table 1.** Conditions and kinetics of cellobiose and glucose oxidation with WT and Δ*PpBBE1* lines grown under standard growth conditions with a 16 h light and 8 h darkness regime (left panel) or in complete darkness (right panel). Determination of glucose and cellobiose in the culture media compared with a dilution series of the sugars in the control growth medium with the DNS assay resulting in a concentration-dependent coloring from dark red (high concentration of reducing sugars) to yellow (no reducing sugars detected) in the left panel. The absorbance of the samples and dilution series shown in the left panels measured at 575 nm is shown in the tables.

anomeric hydroxyl group of the substrate leading to the transfer of a hydride to the N5-position of the flavin. The relevance of this catalytic diade is in accordance with the observed effects on the rate of substrate oxidation (Table 1) and the changes in the pH-profile found for the D396A variant (Fig. 6). The positioning of the anomeric center in the vicinity of the side chain of Y461 and the N5-position of the flavin was confirmed by substrate docking to our crystallographic structure of the protein. In addition, the characterization of the W186F and the S422A variant also revealed that these residues play an important role in organizing the active site, probably by ensuring the correct positioning of the catalytic base D396. This view is supported by the structural network established by these residues, which apparently stabilize the structural topology by interacting with the backbone carbonyl of L397 (W186) and the hydroxyl group of Y398 (S422 via a water molecule), respectively. Q424, on the other hand, may form a hydrogen bond with Y113, but in view of the total loss of enzymatic activity in the Q424A variant, direct stabilization of the transition state seems to be the primary function of this amino acid side chain. This finding is in line with the observation that, according to the crystal structure, Q424 forms only one hydrogen bond, whereas a possible second interaction with the hydroxyl group at the anomeric center of cellobiose is revealed in our docking simulations.

As mentioned in the introduction, we were particularly curious to identify a substrate (or a group of substrates) for PpBBE1 because this would provide information on the 'primordial' function of the BBE-like enzyme family in plants. In this context, the identification of cellobiose and lactose as substrates of PpBBE1 is very intriguing since most members of the BBE-like enzyme family in bacteria and fungi oxidize hydroxyl groups of various carbohydrate substrates, for example, aclacinomycin oxidoreductase from Strep-tomyces species [33] and GOOX from the rot fungus Acremonium strictum [18]. Thus, it is apparent that this activity was already present in early land plants represented by mosses and constituted the starting point for the evolution of BBE-like enzymes in vascular plants, where members of the family are engaged in the oxidation of cyanohydrines and monolignols, as described for A. thaliana [3,4]. The unusual oxidative formation of the berberine bridge in benzylisoquinoline biosynthesis and the cyclization of the monoterpenic moiety of cannabigerolic acid to Δ⁸-tetrahydrocannabinolic acid (THCA), catalyzed by EcBBE and THCA synthase from Cannabis sativa, respectively, have clearly taken this enzyme family to an unprecedented new level of catalytic sophistication and reflect the diverse
array of secondary metabolites found in several plant lineages. On the other hand, the observation that some plants possess BBE-like enzymes with glucose oxidase activity, such as nectarin V from tobacco [7] indicates that the ability to oxidize carbohydrates was also conserved in plants. These observations are in tune with the current concept that biosynthetic pathways have evolved in part by gene duplication and subsequent neofunctionalization of one of the genes to support novel enzymatic modifications of metabolites leading to the enormous variety of compounds found in plants [9,34]. The increasing number of genes encoding members of the BBE-like enzyme family during plant evolution as well as distinct changes in the active site composition suggests that this process was relevant for the evolutionary diversification of this enzyme family in the plant kingdom [2,3].

Our in vitro findings are also in good accordance with the in vivo data obtained from the characterization of a WT and a PpBBE1-knockout strain. The expression of PpBBE1 was high in defined developmental stages, namely chloronema and protoplasts, which originate from protonema tissue. The chloronema harbors high photosynthetic activity characterized by a high number of chloroplasts of large size. On the other hand, caulonema cells possess fewer and smaller chloroplasts that are induced later by auxin and allow spreading of the colony by fast, radial growth relying on the availability of energy and carbon supply [28]. The expression pattern of PpBBE1 reflects the differences in the two protonema tissue types, being highly expressed in chloronema, but not detectable in caulonema. This finding nicely correlates with the recently performed transcriptome analysis of protoplasts [35] as well as of chloronema cells [10,11] that have shown a significant upregulation of carbohydrate and energy metabolism in these early stages of the plant’s life cycle. Our hypothesis that PpBBE is involved in carbohydrate degradation is further supported by the fact that also fungi use cellulose for energy production, which is initially metabolized extracellularly to cellobionic acid and then further degraded by cellobionic acid phosphorylases after transport into the cytoplasm. The resulting products, gluconate and glucose-1-phosphate, are then converted to 6-phosphogluconate and glucose-6-phosphate before entering the pentose phosphate pathway and glycolysis, respectively [36]. Even though this catabolic pathway has never been reported for plants, it is possible that P. patens has similarities to enzymes allowing it to most efficiently use cellulose for energy production [37].

Similarly, PpBBE1 expression was detected in the green parts of the gametophore but not the rhizoids, root-like structures with a similar morphology as caulonema filaments. On transition of the gametophyte to the sporophyte, a transcriptomic switch occurs regarding carbohydrate metabolism and photosynthesis, as the gametophyte has a primary role in photosynthesis, resource acquisition, and long-term maintenance of the plant, while the sporophyte predominantly relies on the gametophyte for both carbon and energy [10,38,39]. This switch is also reflected by the expression of PpBBE1, which is very low or not detectable.
throughout the sporophyte development to the mature spore.

Interestingly, the knockout of PpBBE1 showed no apparent impact on plant morphology and development throughout the whole life cycle in all conditions tested in this study. Even upon growth in darkness, when assimilation via photosynthesis does not take place and supplementation of the media with cellobiose or glucose as carbohydrate source is required for heterotrophic growth, no differences were detected comparing ΔPpBBE1 and WT plants. The effect of glucose and sucrose on Physcomitrella grown in the dark leading to increased caulonema formation has been well studied [28,40]. In our study, the phenotype of cultures grown in cellobiose containing growth media is an intermediate between controls without a carbohydrate source and glucose supplemented cultures although, also here, no difference between the WT and the knockout strains was detected. These findings indicate that cellobiose is metabolized like other carbohydrates such as glucose, used as positive control, or sucrose. As upon heterotrophic growth, not only the phenotype and development of ΔPpBBE1 compared to WT plants but also the concentration of cellobiose or glucose in culture supernatants was unchanged, we conclude that PpBBE1, for which we identified cellobiose as best substrate, is not the only enzyme active in cellobiose metabolism in Physcomitrella. Therefore, we propose that the deletion of PpBBE1 is compensated by the action of other enzymes involved in cellobiose turnover.

**Experimental procedures**

**Materials**

All chemicals and media ingredients were purchased from Sigma-Aldrich (St. Louis, MO, USA), Roth (Karlsruhe, Germany), Merck (Darmstadt, Germany), Fluka (Buchs, Switzerland) or Becton, Dickinson and Company (Franklin, Lakes, NJ, USA) and were of the highest grade commercially available.

All restriction enzymes used were ordered from Thermo Scientific/Fermentas (St. Leon-Rot, Germany) or New England Biolabs (Ipswich, MA, USA), while the Ni-sepharose column material was obtained from GE Healthcare (Chalfont St. Giles, UK).

**Cloning and expression**

For heterologous expression of the PpBBE-gene in K. phaffii, the respective gene was purchased from Thermo Scientific. On ordering, the native sequence was codon optimized for K. phaffii and nucleotides coding for an octahistidine tag were fused to the 3’-end of the gene.

After subcloning into the Escherichia coli pJET vector, PCR amplification was performed in order to remove the native signal sequence identified using SignalP. This PCR product was then cloned into the K. phaffii vector pPICZα, to enable secretion of PpBBE1 in the non-native host. Having linearized the DNA using SacI, electroporation following the instructions provided by the EasySelect™ ExpressionKit (Invitrogen, Waltham, MA, USA) was applied to transform KM71H cells with the gene of interest. These cells were also transformed with pPICK-PDI plasmid DNA to be able to coexpress of the protein disulfide isomerase from Saccharomyces cerevisiae.

Having identified stable and well-expressing clones in small-scale screenings, following the instructions given by [41], large-scale expression in a BBI CT5-2 fermenter (Sartorius, Göttingen, Germany) was performed as described by [42]. After 96 h of MeOH feed (induction time), the pH was set to 8, and cells and medium were separated by centrifugation (3500 g for 20 min). The cells were discarded and the supernatant was incubated with 30 mL of Ni-Sepharose™ (GE Healthcare) Fast Flow column material, which had been equilibrated with binding buffer (50 mM NaH₂PO₄, 150 mM NaCl pH 8) prior to use. To ensure binding of all tagged protein, 1 h of stirring at 4 °C was required, before the column material was filtered and packed into an empty column (XK 26). Having washed with ~150 mL of wash buffer (50 mM NaH₂PO₄, 150 mM NaCl, 20 mM imidazole pH 8) to remove all the unspecifically bound proteins, PpBBE1 was eluted with elution buffer (50 mM NaH₂PO₄, 150 mM NaCl, 300 mM imidazole pH 8). SDS/PAGE analysis was then used to determine the quality of the purification, before pooling the fractions with the highest protein content and lowest amount of impurities (typical yields: 5–7 mg L⁻¹ of culture; ~98% purity). Subsequently, the protein solution was concentrated and the buffer was exchanged to 50 mM HEPES buffer pH 6 using Centriprep® 30 kDa MWCO (Millipore Merck, Burlington, MA, USA).

**Protein denaturation**

To be able to determine the protein concentration based on the characteristic absorption of FAD at about 450 nm, a spectrum of the native as well as of denatured PpBBE1 was recorded. Assuming that the extinction coefficient of the flavin species found in denatured PpBBE1 is equal to the one of 6-S-cysteinyl FMN, an extinction coefficient of 9800 M⁻¹cm⁻¹ could be calculated for native PpBBE1 at 443 nm.

**Photoreduction**

Photoreduction was performed as described by Massey et al. [43]. Under anaerobic conditions, quartz cuvettes
were filled with 20 μM enzyme solution, which also contained 5 mM EDTA as photosubstrate as well as 5 μM 5-deaza-FMN. Having recorded a UV/VIS spectrum of the native, oxidized enzyme, the sample was irradiated and further spectra were recorded at different time points. In order to avoid heat denaturation of the protein, the cuvettes were constantly cooled to 15 °C.

**Determination of the redox potential**

The redox potential of the flavin cofactor was determined using the dye-equilibrium method based on the xanthine/xanthine oxidase system first reported by Massey [19]. Two separate solutions, one containing 500 μM xanthin, 5 μM methyl viologen, and 30 μM PpBBE1 and a second one with xanthin oxidase (about 5 ng) and toluyene blue ($A_{443} = 0.3; E°: +115 mV$) were prepared in 50 mM HEPES buffer pH 7. By mixing these solutions in a stopped flow device (SF-61DX2; Hi-Tech, TgK Scientific Limited, Bradford-on-Avon, UK), placed in an anaerobic glove box, the reaction was started. To monitor the reduction in the product do not have any characteristic spectral properties, a coupled assay with DCPIP (100 μM final concentration in 50 mM HEPES pH 6) was used to determine the initial rates observed upon altering the substrate concentration (cellobiose: 50–1500 μM; lactose: 250–8000 μM), while keeping the enzyme concentration constant. As for the analysis of the pH-optimum, final enzyme concentrations of 10 nM for the wild-type and the Y113F variant and of 200 nM for the remaining variants were used. All reactions were monitored at 600 nm for 120 s and were performed in triplicates.

By plotting the extracted initial velocities vs the respective substrate concentration, $v_{\text{max}}$ as well as apparent $K_M$ values could be determined.

Due to the low reactivity of protein variants, no full Michaelis–Menten curve was recorded. Instead, conversion rates at 1 mM cellobiose were used for an internal comparison and measured in triplicates.

**Substrate screening**

Since the physiological role of PpBBE1 was not known, we performed a screening in 96-well plates using 1.5 mM 2,6-dichloroindophenol in 50 mM HEPES buffer pH 8, containing 1 mM of the following substrate, and 1 μM of purified enzyme: D-saccharose, D-fructose, D-glucose, D-galactose, D-mannose, L-arabinose, D-arabinose, D-sorbitol, D-mannitol, starch, D-maltose, D-lyxose, L-fucose, D-lactulose, D-ribose, D-xyllose, D-trehalose, cellulose, hydroxethylcellulose, lignin, amylose, ribitol (adonitol), D-lactose, D-cellobiose, and cellotriose. The plates were incubated at room temperature and decolorization of the DCPIP solution was analyzed as a function of time.

**pH-optimum**

Having identified two well-accepted substrates for PpBBE1, the pH-optimum was determined in order to be able to study the enzyme characteristic kinetic properties at the optimal pH. Therefore, different buffers in the pH-range of 4-9 were prepared and substrate conversion was analyzed for the wild-type as well as for the variant enzymes. Since both substrate and product do not have any characteristic spectral properties, a coupled assay with DCPIP (100 μM final concentration) was established. By recording the change in absorption at 600 nm, substrate conversion could be monitored and the pH-optimum could be determined. All measurements were performed with constant substrate concentration (1 mM cellobiose) and an enzyme concentration of 10 nm for the wild-type and 200 nm for the variant enzymes, respectively.

**Steady-state kinetics**

Steady-state kinetics of PpBBE1 were measured with cellobiose and lactose for the wild-type enzyme and all active site variants were subsequently only measured with the more efficiently converted cellobiose substrate. A coupled assay with DCPIP (100 μM final concentration in 50 mM HEPES pH 6) was used to determine the initial rates observed upon altering the substrate concentration (cellobiose: 50–1500 μM; lactose: 250–8000 μM), while keeping the enzyme concentration constant. As for the analysis of the pH-optimum, final enzyme concentrations of 10 nM for the wild-type and the Y113F variant and of 200 nM for the remaining variants were used. All reactions were monitored at 600 nm for 120 s and were performed in triplicates.

By plotting the extracted initial velocities vs the respective substrate concentration, $v_{\text{max}}$ as well as apparent $K_M$ values could be determined.

Due to the low reactivity of protein variants, no full Michaelis–Menten curve was recorded. Instead, conversion rates at 1 mM cellobiose were used for an internal comparison and measured in triplicates.

**Presteady-state analysis**

For analysis of the reductive and the oxidative half-reaction, a stopped-flow device from Hi-Tech (SF-61DX2) installed in a glove box (Belle Technology, Cambridge, UK) was used. In both cases, time-dependent spectral changes of the flavin absorption were monitored either with a KinetaScan T diode array detector (MG-6560) or a photomultiplier (PM-61s). Data analysis was then performed with the Kinetic Studio Software (TgK Scientific Limited) by fitting the data points recorded at 443 nm.

To study the reductive half-reaction, observed rate constants for flavin reduction at six different substrate concentrations (100–1000 μM) were determined in 50 mM HEPES pH 6 (at higher substrate concentrations, the reaction was too fast to reliably fit the data to extract rate constants). By plotting $k_{\text{obs}}$ vs the corresponding substrate concentration, a linear increase in reaction rate constants could be observed, making it impossible to fit a limiting reductive rate. In order to allow comparison with the active site variants, a linear fit was applied and the slopes were used for data interpretation.

The oxidative half-reaction was studied by following the reoxidation of the flavin upon mixing enzyme, reduced with 1.2 eq of substrate, with air-saturated buffer (20 °C). To obtain bimolecular rate constants, the rates determined in this experiment were divided by the amount of oxygen dissolved in the buffer (final concentration: 140 μM).
Site-directed mutagenesis

In order to study the reaction mechanism in more detail, active site variants were produced. All constructs were generated from \textit{pICZa}-\textit{PpBBE1} wild-type expression strain applying polymerase chain reaction-based mutagenesis. The amino acid exchanges were introduced with the forward and reverse primers that both carried the desired mutations in the nucleotide sequence (for primer sequences, see Table 2).

After successful cloning and transformation of the mutant strains, expression and purification of the \textit{PpBBE1} variants were performed as described for the wild-type protein.

NMR analysis of the oxidation product

For NMR product analysis, medium-scale turnover reactions were performed, using 3 mL of 10 mM cellulose solution (in ddH2O) and 200 nM enzyme. After 3 h of incubation at 25 °C, full conversion of the substrate was confirmed by thin layer chromatography [MeCN : H2O (85 : 15)]. The samples were then dried in an ISS110 SpeedVac® System (Thermo Scientific, Waltham, MA, USA) and subsequently redissolved in 750 μL of D2O. The last two steps were repeated twice, before NMR analysis was conducted. A Varian (Agilent, Santa Clara, California, USA) INOVA 500-MHz NMR spectrometer (Agilent Technologies) and the VNMRJ 2.2D software were used for all measurements. 1H-NMR spectra (499.98 MHz) were measured on a 5 mm indirect detection PFG-probe, while a 5 mm dual direct detection probe with z-gradients was used for 13C-NMR spectra (125.71 MHz). HSQC and HMB spectra were measured with 16 scans per increment and adiabatic carbon 180° pulses.

Crystallization and data collection

Protein crystals were grown in hanging drop vapor diffusion setups using EasyXtal® 15-Well Tools (Qiagen, Hilden, Germany) and the corresponding crystallization supports (Qiagen). Protein solution (200 μM in 50 mM HEPES buffer pH 6) and crystallization reagent (0.1 mM Mg (OOC)2, 13/14% poly(ethylene glycol) 3350 for wild-type and variant, respectively) were mixed in 2 : 1 or 1.5 : 1 ratio and incubated at 20 °C. After overnight equilibration, streak seeding with crystals from the initial hit was performed. Ten to 14 days later, bipyrimal crystals appeared, which reached their final size after 3 weeks. For cryoprotecting crystals when flash freezing them in liquid nitrogen, 3 μL of 0.1 mM Mg(OOC)2, 13/14% poly(ethylene glycol) 3350, and 40% glycerol were added to the drop containing the \textit{PpBBE1} crystals a few minutes prior to freezing. Crystals were stored in liquid nitrogen and data were collected at 100 K at beamline P11 of the German Electron Synchrotron (DESY, Hamburg, Germany).

Data processing and structure elucidation

Data from the tetragonal bipyramidal crystals were processed with the XDS package [45]. A unique molecular replacement solution was obtained in space group P41212 in Phenix Phaser [46], using a homology model generated on the SWISS-MODEL server [47–49] based on the crystal structure of \textit{A/BBE}-like 15 (pdb code: 4UD8; [3]) as template. The initial solution was refined in cycles of maximum-likelihood least-squares refinement of models modified with Coot [50] using sigmaA-weighted 2Fo − Fc and Fo − Fc electron density maps and including an initial simulated annealing (torsion) step. Details of data collection, processing, and refinement are summarized in Table 3.

Molecular docking

The crystal structure of \textit{PpBBE1} wild-type (WT; PDB: 6EO4) in complex with the bicovalently linked FAD cofactor was used as a basis for substrate-docking experiments. All molecular docking experiments and subsequent MD simulations were performed with the YASARA Structure Suite (YASARA structure version 17.3.30 (Yasara Biosciences [51]). Water molecules were removed from the structure prior to the docking experiment. Molecular docking was conducted utilizing the Autodock Vina Plugin [52] of the Yasara Structure suite. Docking was performed with the rigid receptor while the ligand was flexible with a docking cell lining the active site cavity of \textit{PpBBE1}. The ligand chosen for the docking experiments was the previously identified substrate of \textit{PpBBE1}, cellulose. Two hundred and fifty docking runs were performed with an RMSD cutoff of 1 Å. The resulting docking poses were inspected visually.
Data collection and refinement statistics.

Molecular dynamics simulation

The enzyme complex consisting of PpBBE1, the bicovalently linked FAD cofactor and the previously docked substrate cellobiose were used as the starting structure for molecular dynamics (MD) simulations. MD simulations and analyses were performed using the YASARA Structure suite, version 17.3.30 (YASARA Biosciences [51]). A periodic simulation cell that enveloped the whole enzyme with an additional 5 Å margin in each dimension was used with explicit solvent. The AMBER14 force field [53] was applied and long-range electrostatic potentials were calculated using the Particle Mesh Ewald (PME) method and a cutoff of 7.864 Å [54,55]. AutoSMILES utility was used to attribute force field parameters to PpBBE1 and FAD [56]. The hydrogen-bonding network optimization was carried out using the method of Hooft and coworkers [57], and pK_a values at pH 6 were assigned [58]. The simulation cell was filled with water containing 0.9% of NaCl (density of 0.993 g·mL⁻¹). Solvent was relaxed and the system was subsequently energy minimized using steepest descent minimization to remove conformational stress, followed by a simulated annealing minimization to convergence (< 0.05 kJ·mol⁻¹ per 200 steps). Integration time steps were 1.33 and 4 fs for intra- and intermolecular forces, respectively. Subsequently, MD simulations at 310 K were performed, whereby integration time steps for intramolecular and intermolecular forces of 1.25 fs and 2.5 fs were applied, respectively. MD simulations were carried out over a time span of 12.5 ns. A restraint was added to the force field to maintain a catalytically competent complex at the active site. A restraining spring with a force of 100 SFC was applied combined with a distance restrain of 3 Å between the catalytically relevant hydrogen (H1*) of the substrate and the N5 of FAD. Additionally, an angle of 105° was set between N10-N5 and the previously mentioned hydrogen atom (H1*) of the substrate. The restraints were set following the findings of defining general distances and angles for catalysis-competent complexes of flavoenzymes and their respective substrates [59]. Analysis of MD simulation results included measuring general distance traces and hydrogen-bonding events of cellobiose with predefined amino acid side chains of PpBBE1 that determine the structure of the active site.

Secretome analysis

For secretome analysis, the liquid culture supernatant of a P. patens line secreting human recombinant Erythropoietin (IMSC40216, www.moss-stock-center.org) [60,61] was precipitated with TCA as described in [61]. Sample preparation and subsequent SDS/PAGE as well as mass spectrometry were performed as described in [62]. Raw data processing and database search were performed against the V1.6 protein models (www.cosmoss.org) using Mascot software (Matrix Science, Boston, MA, USA).

Physcomitrella patens moss material and growth conditions

For all experiments, P. patens (Hedw.) B.S. ecotype ‘Gransden 2004’ was used. This is the same strain that was used for genome sequencing [63] and was deposited at the International Moss Stock Centre (IMSC, http://www.moss-stock-center.org) under accession number 40001. The ΔPpBBE1 lines described in this study were cryopreserved according to [64] and are available from the International Moss Stock Centre (IMSC) with the following accessions: 40829 for ΔPpBBE1#80, 40830 for ΔPpBBE1#83, and 40831 for ΔPpBBE1#100.

The material was axenically cultured in Knop medium (250 mg·L⁻¹ KH₂PO₄, 250 mg·L⁻¹ KCl, 250 mg·L⁻¹ MgSO₄ × 7 H₂O, 1 g·L⁻¹ Ca(NO₃)₂ × 4 H₂O, and 12.5 mg·L⁻¹ FeSO₄ × 7H₂O, pH 5.8; [65]) supplemented with microelements [66] cultivated in a growth chamber under controlled conditions (25 °C) with a 16 h : 8 h, light:dark regime at a light intensity of 70 μmol·m⁻²·s⁻¹ as described in [67]. For supplementation of media with carbohydrates, cellobiose and glucose were added to a final

---

concentration of 0.5% (w/v). For salt stress experiments, NaCl was added to the solid culture media in concentrations of 500 mM, 750 mM, and 1 mM. For the adjustment of dry weight in *P. patens*, 10 mL of liquid culture was removed prior to subculturing and filtered through gauze (Miralcoth, Calbiochem, Schwalbach, Germany). The dry weight was determined after drying the sample at 105 °C for 2 h. For the induction of sporophytes, the Petri dishes were transferred to inducing conditions according to [68]. For dark treatment, protonema in liquid medium were grown for 3 weeks, whereas gametophores on solid medium were incubated in a light-tight box in a growth chamber for 4–6 weeks. Additionally, spot inocula of protonema were grown in darkness for 4 weeks either directly after inoculation or after preculture under standard light conditions for 2 weeks.

**Generation and validation of Δ*PpBBE* lines**

For construction of the *PpBBE1*-knockout construct, genomic DNA was isolated according to [69] and used as template in an overlap extension PCR. Fragments of exon 1 and exon 3, together with the respective 850 bp flanking regions, were amplified in separate PCR reactions, with the reverse primer for exon 1 (first 38 bp) and the forward primer for exon 3 (last 37 bp) carrying an overlapping sequence with the flanking regions of the ntpII selection cassette, which should replace the missing gene fragment (Fig. 9A, Table 4). In a second PCR reaction, all three fragments were fused, before subcloning the newly generated DNA to pJET and transforming the recombinant plasmid with *E. coli* top 10 cells for further amplification. Since sequencing of the subcloned DNA revealed a mutation, the error was removed in an additional mutagenesis PCR reaction (Primers see Table 4).

Prior to the transformation procedure, the *PpBBE1*-knockout construct was cut from the pJET vector using *SphI* and *PacI*. Protoplast isolation, transformation, and regeneration to obtain stable knockout plants were performed as previously described [23] using 40–50 μg of DNA. Selection was done in two successive cycles by transformation (Primers see Table 4). In a second PCR reaction, all three fragments were fused, before subcloning the newly generated DNA to pJET and transforming the recombinant plasmid with *E. coli* top 10 cells for further amplification. Since sequencing of the subcloned DNA revealed a mutation, the error was removed in an additional mutagenesis PCR reaction (Primers see Table 4).

A qPCR-based method [26] was used. The 5′-HR region and the 3′-HR region were amplified using the primer couples qPCR_BBE_5HR_fwd and qPCR_BBE_5HR_rev and qPCR_BBE_3HR_fwd and qPCR_BBE_3HR_rev, respectively, whereas transcripts of the ntpII selection cassette and the single copy gene pCLF (internal control) were generated using the primer couples q_npt_fwd and q_npt_rev and pCLF_5915_qf and pCLF_5981 qr or pCLF_7739_qf and pCLF_7804_qr, respectively. From these results, the copy number of *PpBBE1*-knockout genes could be determined.

As control lines, a WT strain and a line with a confirmed single integration of the ntpII selection cassette were used. The complete list of primers used for the cloning of the *PpBBE1*-targeting construct and molecular validation of the transgenic plants is shown in Table 5.

As the DNA content of *Physcomitrella* is known, haploidy of the Δ*PpBBE1* lines could be confirmed in a fluorescence-based assay. Nuclei prepared from 10 to 30 mg freshly chopped protonema material were stained with a 4′,6-diamidino-2-phenylindole (DAPI)-containing buffer [25] and analyzed using a Cyflow® Space flow cytometry system (Partec, Münster, Germany) as described in [70].

**Qualitative and quantitative determination of cellulbiose and glucose**

In order to qualitatively assay the cellulbiose and glucose content of solid media, plates were stained with a solution of 0.1% (w/v) congo red. After washing with a 0.5 m

**Table 4. Primers used for the generation of the Δ*PpBBE1* strain.**

| Primer     | Sequence                              |

NaCl solution for five times, for better visualization of lighter stained zones, the pH was adjusted to 2. Benedict’s test, using 1 mL of the sample and 200 μL of Benedict’s reagent, performed according to [71], was used to qualitatively analyze the liquid culture supernatants. Here, a color change from blue to red, caused by the precipitation of copper sulfate, indicates the presence of reducing sugars in the solution. For quantification of cellobiose and glucose in the liquid media, a DNS assay was performed as described [72]. 250 μL of sample was mixed with 250 μL of 0.005 M sodium acetate buffer pH 4.8 and 750 μL of DNS reagent. Photometric quantification was done at 575 nm for all samples and appropriate standard dilution series for each sugar. Additionally, sugars were quantified using the glucose test strips of the Reflectoquant system (Merck).

**Image acquisition**

Images were acquired with an ICc1 or Mrc5 CCD camera (Zeiss, Oberkochen, Germany) at an Olympus SZX7 binocular microscope (Olympus, Tokyo, Japan) or an Axiovert S100 (Zeiss), AXIOVISION Software Version 4.8 (Zeiss) was used for imaging.

**Acknowledgements**

This work was supported by a grant from the Austrian Science Fund (FWF) through grants W901 (Doctoral Program ‘Molecular Enzymology’) and P28678 and by the Excellence Initiative of the German Federal and State Governments (EXC 294 to RR). The authors are also grateful for the support by the interuniversity program in natural sciences (NAWI Graz). We are very grateful to Prof. Hansjörg Weber (TU Graz) for his assistance in recording NMR spectra, Richard Haas for his excellent technical assistance, Greenovation GmbH for providing the EPO strain, Dr. Juliana Parsons for preparation of the protein samples, Prof. Dr. Andreas Schlosser for MS measurements, and Anne Katrin Prowse for proof reading of the manuscript.

**Author contributions**

PM initiated the project; MT, RR, GW, BD, and PM designed the experiments and interpreted the data. MT expressed and purified PpBBE1 and performed analytical, biochemical, and kinetic experiments. MT and AW crystallized proteins and determined the 3D structure of PpBBE1. GW analyzed organization and expression of the PpBBEs and generated knockout moss mutants. GW and JK analyzed the moss mutants. SNWH analyzed the secretion of PpBBE1 into the moss culture medium. JN performed docking; MT, AW, and PM wrote the manuscript with the help of RR and GW.

**Conflict of interest**

The authors declare no conflict of interest.
