ABSTRACT
We present an analysis of 9 yr of Catalina Surveys optical photometry for 1.4 million spectroscopically confirmed SDSS galaxies. We find 717 outburst events that were not reported by ongoing transient surveys. These events have time-scales ranging from weeks to years. More than two-thirds of these new events are found in star-forming galaxies, while such galaxies only constitute ∼20 per cent of our sample. Based on the properties of the hosts and events, we find that almost all of the new events are likely to be associated with regular supernovae. However, a small number of long time-scale events are found among the galaxies containing AGNs. These events have similar properties to those recently found in the analyses of light curves of large samples of AGNs. Given the lack of such events among more than a million passive galaxies in the sample, we suggest that the long outbursts are associated with supermassive black holes or their environments.

Key words: galaxies: general – galaxies: active – galaxies: photometry – supernovae: general.

1 INTRODUCTION
Our understanding of the nature and range of variability in galaxies has evolved significantly over the past decade. These advances are largely due to the long-term monitoring of millions of galaxies by wide-field transient surveys, such as the Catalina Real-time Transient Survey (CRTS; Drake et al. 2009; Djorgovski et al. 2012), the Panoramic Survey Telescope and Rapid Response System (PS1; Chambers et al. 2016), and the Palomar Transient Factory (PTF; Law et al. 2009).

The most common cause for rapid, transient variations in the brightness of galaxies is supernovae (SNe). These objects provide insight into the final stages of stellar evolution, and, in the case of type-Ia SNe, provide uniform standard candles for measuring cosmological distances (Sandage & Tammann 1982). To date, more than 25 000 SN candidates have been discovered.1

In the past 5 yr, SN discovery rates have climbed from hundreds to thousands of events per year. This increase is almost exclusively due to the advent of modern transient surveys. This increase has been so dramatic that it far outstrips our ability to spectroscopically confirm the nature of most transient discoveries. Even with new spectroscopic surveys, such as the Public ESO Spectroscopic Survey for Transient Objects (PESSTO; Smartt et al. 2015), less than 20 per cent of new SN candidates are confirmed. This lack of confirmation has become known as the ‘follow-up problem’.

Aside from SNe, it is well known that many galaxies harbour massive black holes that undergo accretion processes that are often observed as nuclear variability. The variations of these sources are usually a few tenths of a magnitude, but can become compounded to variations of more than a magnitude on long time-scales (MacLeod et al. 2012, Graham et al. in preparation). In very rare cases, these active galactic nuclei (AGNs) have recently been found that appear to turn-on or off over time-scales of years (MacLeod et al. 2016; Gezari et al. 2017; Stern et al. 2018.). This so called ‘changing-look’ type behaviour have been observed at low levels in target studies of Seyfert galaxies for decades (e.g. Tohline & Osterbrock 1976; Osterbrock & Shuder 1982; Goodrich 1989), but has only recently been observed in luminous quasars. The advent of large surveys has confirmed this as a wide spread phenomenon.

A moderately large number (72 as of 2018 January)2 of transient events have also been associated with the tidal disruption of stars by massive nuclear black holes (Rees 1988; Gezari et al. 2003; Auchettl, Guillochon & Ramirez-Ruiz 2017). Still further events

3https://tde.space/
temporal variability associated with AGNs continue to have an unclear origin (e.g. Meusinger et al. 2010; Drake et al. 2011a). The possible causes of these AGN-related events are believed to include microlensing events, stellar mass black hole mergers, and superluminous SNe (Lawrence et al. 2016; Graham et al. 2017).

The increased photometric monitoring of millions of galaxies by transient surveys has resulted in a significant increase in the number of transients found in galaxies. This increase has resulted in a smaller fraction of transients being spectroscopically confirmed. This is a trend that will almost certainly continue with even larger transient surveys, such as the Zwicky Transient Facility (ZTF; Bellm 2014) and the Large Synoptic Survey Telescope (LSST; Ivezić et al. 2008). The fact that we are unable to spectroscopically confirm the nature of most transients greatly increases the importance of any prior information that can be garnered from existing data.

Archival information from large spectroscopic surveys, such as the Sloan Digital Sky Survey (SDSS; Albareti et al. 2017), can aid our understanding of the nature of current and past transient events. For example, the spectroscopic redshift of a galaxy gives us a distance estimate for events that appear associated with it. The combination of this distance with extinction values and a light curve enable us to estimate the energetics of an event. Furthermore, the presence of emission lines in the host spectrum can be used to estimate the star formation rate and metallicity of the host. In turn, these pieces of information can often be used to constrain the type of event. For example, type-Ia SNe have a well-constrained set of light curve shapes and are found in all types of galaxies. In contrast, core collapse SNe (hereafter CCSNe) are generally believed to be the product of massive stars with short lifetimes and are observationally very rare in ellipticals (van den Bergh & Tammann 1991).

In this paper, we investigate what can be learnt about the variability in galaxies by combining existing photometry and spectra for more than a million galaxies. We specifically search for significant flares and outburst events that may have been missed in large surveys due to selection biases or assumptions about galaxy variability. We investigate the general nature of the galaxies hosting significant outbursts. We pay particular attention to the presence of flaring events like those found by Lawrence et al. (2016) and Graham et al. (2017) in AGNs. Finally, we consider how archival data may help mitigate the follow-up problem in current and future large transient and variability surveys. We adopt $H_0 = 72$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.73$, $\Omega_L = 0.27$ and Vega magnitudes throughout.

2 DATA

In order to investigate the general nature of flaring phenomena in galaxies, it is necessary to begin with a large, clean, sample of sources. Detection sensitivity requires that the sources have been monitored with the time span and cadence required to discern such events from other types of variability and noise sources. The combination of photometry from the Catalina Surveys with SDSS spectroscopy provides us with this for more than a million galaxies.

2.1 Catalina photometry

The Catalina Surveys consist of two separate surveys that use the same data for different purposes. These consist of the Catalina Sky Survey (CSS) which searches for optical transients (Drake et al. 2009). The NEO survey began taking observations with three telescopes in 2003. Each telescope was run as a separate sub-survey. These consisted of the 0.7m Catalina Schmidt Survey (CSS) and the 1.5 m Mount Lemmon Survey (MLS), both in Tucson, Arizona, and the 0.5 m Siding Spring Survey (SSS) at Siding Spring, Australia. CRTS began by processing data from CSS in 2007 and later added data from MLS and SSS.

Each of the Catalina telescopes takes observations using a grid of fields that tile the sky. These surveys, when combined, cover most of the sky between declinations $\delta = -75$ and $+ 65^\circ$. However, regions within $\sim 15^\circ$ of the Galactic plane are generally avoided due to crowding.

The original MLS and CSS 4k$^2$ cameras have recently been upgraded to increase their field of view. However, here we only consider data taken in the original configuration, where MLS and CSS survey images covered 1.2 deg$^2$ and 8.2 deg$^2$, respectively. We do not consider SSS data since this generally does not overlap with the SDSS footprint.

Almost all Catalina observations are taken in sequences of four images covering the same field each 10 min. Isophotal photometry is obtained for all sources in each observation using the SExtractor images covering the same field each 10 min. Isophotal photometry is taken between 2007 January 1 and 2016 April 28. We do not consider earlier Catalina photometry since some of it was measured using a larger aperture that caused inaccurate photometry when neighbouring sources were present.

Most of the photometry used in this work is publicly available as part of Catalina Surveys Data Release 2 (CSDR2). However, some additional more recent photometry is also included, which will soon be made available as part of CSDR4 (Drake et al., in preparation).

2.2 SDSS spectra

The SDSS has operated for well over a decade and undertaken multiple spectroscopic surveys. For this analysis, we selected spectroscopic data from SDSS DR13 (Albareti et al. 2017) as our reference set. This was the most recent SDSS data release at the time of the analysis and contains 4.4 million optical spectra of QSOs, galaxies, and stars. This dataset includes spectra from the SDSS legacy survey (York et al. 2000), as well as those from the new spectrograph used for the Baryon Oscillation Spectroscopic Survey (BOSS) (Dawson et al. 2013), and the Sloan Extended Quasar, ELG, and LRG Survey (SEQUELS) program (Albareti et al. 2017 and references therein).

The original SDSS legacy survey spectra have a wavelength range of 380–920 nm with resolution $R \sim 2000$ and 3 arcsec fibres, while the BOSS spectra cover 360–1000 nm with $R \sim 2000$ and 2 arcsec fibres. The legacy survey targeted what is known as the Main Galaxy Sample (MGS). This consists of bright galaxies with Petrosian magnitude $r_P \leq 17.77$ (Strauss et al. 2002), a Luminous Red Galaxies

3http://www.lpl.arizona.edu/css/

http://crts.caltech.edu/ Note: CSS in this work only relates to this telescope.

http://catalinadata.org
example, a magnitude we are insensitive to most outbursts in more distant galaxies. For SDSS galaxies, we select the 1.7 million sources with redshifts \( z < 0.5 \). We specifically limit our sample to the nearer sources since we are insensitive to most outbursts in more distant galaxies. For example, a magnitude \( V_{\text{CSS}} = 19.5 \) galaxy at \( z = 0.5 \) has \( M_V = -22.5 \) (ignoring extinction). Thus, to detect an outburst in such a galaxy, the event would need to be among the few brightest known superluminous SNe. Additionally, since more distant galaxies are, on average, fainter, they tend to have lower signal-to-noise ratio spectra.

The detection of flaring events in the presence of AGNs has already been addressed for CSS data for 900 000 source by Graham et al. (2017). That work revealed many AGNs undergoing large flaring events. Here, we aim to test whether similar outbursts also occur in quiescent galaxies. However, we do not remove the small fraction (<4 per cent) of SDSS galaxies that are also spectroscopically classified as containing AGNs.

Matching the locations of the \( z < 0.5 \) SDSS DR13 spectroscopic galaxy sample to those among the 200 million sources in the CSS catalogue, we find 1.46 million matches within 5 arcsec. Since our aim is to find outbursts in the light curves of these sources, we sub-select the galaxies with 20 or more nights of CSS photometric observations. This selection reduces the total number of SDSS galaxies with CSS light curves to 1.43 million. Some of the matched galaxies are duplicates due to overlap between CSS fields. In the final dataset, there are 1.42 million unique CSS sources having SDSS spectra.

We also matched the nearby (\( z < 0.5 \)) SDSS galaxy sample to sources from the MLS survey. This data only covers objects near the ecliptic, where there are only 377 000 matches with SDSS. The MLS photometry is also much sparser than CSS. Among these matches only 152 000 have more than 20 nights of MLS observations. Since the number of SDSS galaxies with MLS light curves is only \( \sim 10 \) per cent that of the CSS set, we will primarily concentrate our analysis on the CSS sample.

3 CANDIDATE SELECTION

In order to select a set of photometric outbursts, among the sample of 1.4 million spectroscopically confirmed galaxies with significant CSS photometry, we must first understand the range of photometric uncertainty and the extent of individual object variability. Once we understand these, we can then identify and remove sources of noise to minimize any impact they might have on the results.

3.1 Determining photometric uncertainties

Our main goal in this work is to find galaxies exhibiting flaring events among the SDSS sample of spectroscopically confirmed galaxies. Such events may be due to SNe, tidal disruption events (Rees 1988), AGN activity, microlensing (Lawrence et al. 2016), or other hitherto unknown sources. Since our aim was to find outbursts in general, we decided to minimize assumptions about the shapes of the events. Thus, our initial selection of candidates was based on statistical significance rather than model fitting.

In order to select galaxies exhibiting significant changes in brightness, it is necessary to understand the underlying degree of scatter in the photometric data. Based on reduced \( \chi^2 \) values for fits to periodic variable light curves, Drake et al. (2014) showed that the photometric uncertainties given for CSS photometry in CSDR2 are generally overestimated for bright sources and underestimated for fainter sources. Graham et al. (2017) further quantified the values required to correct the average magnitude-dependent effect. Nevertheless, since these corrections are averaged over \( \sim 200 \) million objects distributed across most of the sky, they fail to fully represent the low-level variations in individual light curves due to differences in crowding, airmass, weather, etc. Thus in this work, rather than correcting the uncertainties using the values in Graham et al. (2017), we instead measure the scatter in the photometry for each light curve as an initial estimate of the true uncertainty.

As a starting point, we assume the uncertainties are normally distributed and use the standard deviation for each source as the measure of scatter. In the left-hand panel of Fig. 1, we plot the distribution of CSS photometric uncertainties for a sub-sample of 200 000 of the SDSS galaxies. Evidently, galaxies brighter than \( V_{\text{CSS}} = 16 \) typically have \( \sigma < 0.04 \) mag and at \( V_{\text{CSS}} \sim 20 \) galaxies have \( \sigma \sim 0.5 \) mag.

We note that the presence of real underlying variability, such as due to AGNs, will tend to skew or broaden the observed distributions as will outliers due to noise sources. To mitigate the effect of outliers we perform a 3\( \sigma \) clipping on the measurements. We then recalculate the scatter from the clipped distribution. The clipping process typically only removes a few outliers from each light curve.

The outliers themselves are mainly bright points caused by artefacts, such as saturated columns, internal reflections and satellite trails, as discussed in the next section.

We do not expect that long time-scale variability will be significantly affected by the clipping process. For example, the long time-scale variability typical of AGNs (Macleod et al. 2012) will tend to broaden the distribution beyond the true photometric uncertainties, but few if any points will be removed.

3.1.1 Sources of photometric outliers

As noted above, our simple statistical selection of outbursts is only dependent on the distribution of photometric measurements. The light curves can be affected by both real outbursts as well as noise sources within the images. These two sources both generally produce a long positive tail in the measurement distributions. It is therefore necessary to separate the noise sources from the actual outbursts.

One of the main sources of photometric outliers are image artefacts due to very bright stars. Such stars can cause saturated lines, blooms and haloes that can affect the measurements of both nearby and distant sources. Additionally, the effects caused by bright stars can occur intermittently, since a bright star may not saturate an image taken in poor seeing, or when the sky background level is low.

As part of the CRTS transient search processing, all CSS data is run through a pipeline that automatically masks objects in close proximity to very bright stars (Drake et al. 2009). The values used to veto transient candidates near bright stars are the same as those used to cull AGN flare candidates near bright stars as presented in Graham et al. (2017). That process was also adopted to veto
flare candidates in this work. In the right-hand panel of Fig. 1, we show the scatter for the small fraction of galaxies that are in close proximity to saturated stars. This small group (<1 per cent) of galaxies contributed a large fraction of all sources having significant scatter. In addition, the brightest stars also introduce noise into the light curves of much more distant sources via line-bleeds. Indeed, since the field of view of the Catalina CSS camera spans more than two degrees, these line-bleeds also can affect light curves of sources that are very far from the saturated stars.

Inspecting a number of the full Catalina images, we found that the line-bleeds are generally contained to within tens of arcseconds along right ascension (even for stars with $V_{\text{CSS}} < 8$). A smaller effect was also measured along declination for saturated stars. By using the known locations of bright stars in the Tycho catalogue we compiled a list of galaxies within our sample that could be affected by bleeds from saturated stars lying anywhere within their field. This list contains only $\sim 17,000$ galaxies among the 1.4 million CSS-SDSS galaxy sample.

Considering the full observational situation it is self-evident that this list would not contain all affected galaxies. For example, the degree of saturation-induced bleeding alone depends on the colour of the star as well as changes in the background sky level, etc. In fact, the complexity and diversity of the effects caused by bright stars limits our ability to algorithmically mitigate the sources of all outliers. Inspection of the light curves and images showed us that many additional light curves were affected by related effects as well as unrelated noise sources. Specifically, there were many light curves with photometry that was affected by reflections, cosmic rays, and satellite trails. Thus, rather than simply removing galaxies that were potentially affected by neighbour saturated stars, we concluded that it would eventually be necessary to inspect the images for every single outburst candidate.

The need for the final by-eye image verification was not surprising, since even modern transient surveys employing machine learning classification techniques still require human scanners as the final step in transient confirmation. This is due to the fact that both transients and artefacts are generally rare (sometimes unique). Their scarcity often places them in the same poorly defined region of the detection parameter space, where the measured observables are insufficient for a unique classification without the addition of contextual data (such as can be gained from the images, historical light curves, multiwavelength data, etc.).

### 3.2 Initial candidate selection

#### 3.2.1 Information from known events

In order to investigate the methods and thresholds that might be appropriate for finding outbursts, we decided to extract the light curves for every galaxy with an SDSS spectrum and a known SN candidate. Although we are not specifically searching for SNe, such sources clearly provide the largest and most well understood population of outburst events within galaxies.

We matched the online Rochester SN catalogue (Gal-Yam et al. 2013), consisting of $\sim 25,000$ known SN candidates, with the spectroscopically confirmed SDSS galaxies in our sample. In total, this dataset consisted of 3131 unique SDSS galaxies with SN candidates and CSS light curves. Due to repeated spectroscopic observations, there are actually 3464 individual SDSS spectra for these hosts. Additionally, due to overlap between CSS fields, these galaxies match 3,207 separate CSS light curves.

Of the 3131 SN candidates, a large fraction are undetectable within the Catalina light curves as they occurred before the galaxy was monitored, or during observing gaps. Overall, only 1732 of the SN candidates in SDSS confirmed galaxies were discovered within the range of dates analysed here. For each of these galaxies, we extracted the CSS light curve. We then plotted and inspected each. Many of the SN candidates show no sign within CSS light curves since they are well offset from the cores of their hosts. Nevertheless, even when there is no evidence...
for the SN candidates in the CSS light curves, these galaxies can still provide a useful sample for testing and understanding the properties of SN host galaxies. The set of hosts where the SN candidates were clearly present within the CSS light curves provided us with a means for determining whether our detection method and threshold was actually selecting the events.

3.2.2 Filtering candidates

Overall, based on our sigma clipping, we know that outliers occur at a rate of around 1 per cent of the data. Nevertheless, in some cases there can be dozens of outliers. Thus, with more than a million light curves, the selection of outburst candidates based on a single night is impractical. Significant additional evidence would be required to believe the validity of any such candidates. Likewise, the expected false positive rate due to two consecutive nights of high measurements is also too high to have confidence in candidates. However, the probability of a third night containing an outlier in a sequence of between 20 and 200 nights is highly unlikely (\(\lesssim 0.1\) per cent, assuming their occurrence is uncorrelated). Thus, our initial criterion for selecting outburst candidates was to require that each candidate was detected on at least three contiguous nights of observations.

This selection enables us to mitigate most of the problems due to random artefact occurrences. Nevertheless, in some cases outliers due to spurious sources are also correlated in time – for example, due to lunar cycles, seasonal variations in observational airmass, weather patterns, etc. Thus, rather than, for example, simply selecting sources that are outliers based on the presence of, for example, three \(> 3\sigma\) contiguous detections, we decided to estimate the likelihood of each detection based on a normal distribution. To simplify the process we only calculate the probabilities for sequences of measurements where there are at least three values \(> 1\sigma\) above the median brightness. Such sequences occur in a random sequence of normally distributed data \(\sim 0.4\) per cent of the time.

3.2.3 Modelling coincidences

We carried out simple numerical simulations involving the production of a few hundred thousand light curves with purely Gaussian deviations. We found that \(\sim 30\) per cent of these light curves meet our initial selection criteria. Such a low threshold enables us to potentially retain some sensitivity to selecting events with long time-scales when the individual nights have only marginal significance. However, it was obvious that much more stringent criteria were required to remove the coincidental detections.

The initial selection process was run on the known SN candidates as well as on the full set of 1.4 million galaxy light curves. In total, \(\sim 400\,000\) of the light curves had at least three contiguous \(1\sigma\) deviations (in good agreement with our expectations). For all the light curves meeting the initial threshold, we then estimated the probabilities, \(P\), of each set of high points randomly occurring. In each case the combined nightly average magnitudes were assumed to be normally distributed.

In Fig. 2, we plot the distribution of expected probabilities for each of the candidate outbursts in the initial selection as well as those for the 1232 previously known SNe candidates that meet our initial selection criteria. This plot also shows the number of objects and probabilities expect based on our simple numerically simulated light curves with pure normally distributed data. One can see that for events with \(\log(P) > -11\), the number of candidates selected is consistent with that expected from our simulated normally distributed data. However, the actual distribution of probabilities for the initial 400000 selected sources is very different from the pure Gaussian simulation. The observed distribution shows a strong tail. This is due to a combination of real variability, the presence of outliers, and the heteroscedastic nature of photometric uncertainties.

3.3 Final candidate selection

As noted above, based on our initial investigation there was a clear need to inspect the data relating to each candidate. To decrease the
number of spurious outbursts, we decided to inspect both the light curves and the images of each candidate.

3.3.1 Light-curve inspection

To select good candidates from the initial large set, we firstly inspected the light curves of a few hundred random galaxies as well as all 3207 galaxies containing previously known SN candidates. We paid particular attention to the light curves of galaxies where the SN candidate were know to occur during our analysis period.

This initial inspection led us to select only candidates where the chance of random occurrence was log(P) < −8.5. This threshold was determined based on requiring that known SN candidates should be selected via the presence of the actual outburst. We determined that events with peaks occurring within 100 d of the candidate’s discovery date were likely due to that event. In such cases there is only a ~6 percent chance of any of these events occurring randomly given that span of the observations is ~3500 d.

We found that most of the known SN candidates that were among the initial 400 000 objects, though a number were missed by the log(P) < −8.5 selection as they did not exhibit significant sign of the SN in the light curve.

Having decided on our probability threshold, we inspected the light curves of every source with log(P) < −8.5. Of these, > 90 per cent of the candidates were rejected simply by considering the presence of variability (due to real sources or noise artefacts) in the light curves. We selected a refined set of candidates by further considering the shapes of each outburst candidate, additional measurements surrounding each candidate event and coincidence in MLS data. Overall, this process led to an initial set of 1090 new outburst candidates.

3.3.2 Image inspection

After our initial selection of candidates based on light curve data, we inspected the images associated with the peak for each candidate. This process enabled us to remove candidates due to image artefacts (such as saturated columns and blending).

For every candidate, we extracted cutouts 5 arcmin across for the images taken within 10 d of the photometric peak. For the initial set of 1090 CSS outburst candidates this consisted of 7638 separate images. After removing events due to image artefacts, we were left with a final set of 692 outburst candidates.

While examining the images of the outburst candidates we noted that a small fraction (~10 per cent) clearly showed the presence of a new source that was separated from the core of the host galaxy. We were able to verify that these were indeed real objects by comparing the outburst images with the deeper, higher resolution, images of the hosts from SDSS. We note that all of the SDSS images were taken prior to the CSS data, so the presence of new sources gives us very high confidence that these detections are genuine. Furthermore, since TDEs and AGN flares are only expected in the cores of galaxies, these particular sources are all likely to be SNe. In Fig. 3, we show an example of likely SN CRTS_OBC_341. Here the new source is clearly seen offset from the core of the galaxy KUG 1241 + 301.

For the bulk of the outburst candidates, the lack of a new source is expected since sources that are resolved from their host galaxies should be detected as separate new sources. It may be possible to resolve additional outbursts from their hosts using image subtraction. However, since most of the host galaxies with new candidates appear relatively compact, and the CSS pixels are large (2.5 arcsec), this is unlikely to lead to many with statistically significant offsets.

4 OUTBURST CANDIDATES

In Table 1, we present the parameters for each of the 692 new CSS outburst candidates. This table includes the length and significance of each outburst candidate as well as an assessment of the quality of each candidate based on the inspection of the light curve and images. Most of the 80 candidates with a quality value of III have log(P) > −12 and are thus potentially statistical coincidences. In some cases a candidate is deemed of higher quality than the probability would suggest because it is also seen in MLS photometry.

In Fig. 4, we present the full CSS light curves and a zoomed outburst region for a sample of the new outburst candidates that passed both light curve and image inspection. In each case, we include the 1σ lower limit used to detect outbursts. We do not include individual measurement uncertainties since our selection method is based on the distributions rather than individual uncertainties.

In most cases, the events are seen to last around 100 d in the observed frame. This time-scale is completely consistent with expectations for SNe. However, in a few cases the events are significantly longer. For example, the outburst of CRTS_OBC_454 (Fig. 4, set 4) appears to have lasted for at least 400 d. Such events are not consistent with most types of SNe. However, they are consistent with some type-IIn SNe that can have outbursts that last for years (e.g. Smith et al. 2010; Rest et al. 2011).

In Fig. 5, we show the scatter of the newly selected outburst candidates compared to the previously known SN candidates. Interestingly, the new candidates are generally found to exhibit smaller photometric scatter than those galaxies with known SN candidates. Also, as expected, the scatter among the new candidates is far smaller than the objects expected to be affected by nearby bright stars (as previously shown in Fig. 1). That is to say, almost all of the new candidates have σ < 0.2 mag, while many of the galaxies affected by nearby saturated stars have σ ~ 0.8 mag.
Table 1. Properties of CSS outbursts.

| ID       | RA (J2000, deg) | Dec (deg) | V_{CSS} | M_V | MJD_{peak} | Length (d) | Signif | Log(P) | Nights | Quality |

Note. The full table will be available online.

Column 1: CRTS outburst candidate ID.
Columns 2 and 3: Source coordinates.
Columns 4 and 5: Apparent and absolute magnitudes for the peak of the outburst, respectively.
Columns 6: MJD of the outburst peak.
Column 7: Time span over which the candidate outburst was detected about 1 day.
Column 8: Total significance in sigma of the detections during the outburst time span.
Column 9: Probability of false detection assuming normally distributed data.
Column 10: Number of nights when the outburst was detected above 1\(\sigma\).
Column 11: Quality of the outburst candidate based on the inspection of light curves and images as well as the presence of detections in MLS data. The values are as follows: I – high confidence event; II – moderate confidence event; III – low confidence event.

\(\text{a}^\text{Outburst is also detected in MLS observations.}\)
\(\text{b}^\text{Source is resolved from the host galaxy.}\)
\(\text{c}^\text{Long time-scale event.}\)

By subtracting the median host magnitudes from the peak observed magnitudes for each event, we derive estimates for the brightness of each outburst. By using distances derived from the known host redshifts, we also determined the peak absolute magnitude. However, these estimates are lower limits since, while we have corrected for foreground extinction (using Schlegel, Finkbeiner & Davis 1998, reddening maps), the amount of extinction the outbursts suffer within the hosts is unknown.

In Fig. 6, we plot the magnitude distributions for the outbursts and their hosts. As expected, the outburst absolute magnitudes generally range from \(M_{V} \sim −14\) to \(−20\). This is completely consistent with the brightness distribution for regular SNe (Richardson et al. 2002). However, there are a few brighter events that we will discuss later. Overall, the outbursts are found to be asymmetrical. Those events where the outburst shape is well defined all have much shorter rise times than declines. Such features are a general feature of all types of SNe light curves, even though there is significant diversity in the exact shapes. In contrast, Graham et al. (2017) found a few examples of QSO flares where the rise and decline times were similar.

5 NATURE OF THE HOST GALAXIES

SDSS DR13 provides details such as age, metallicity, star formation rate, and mass for most of the galaxies with spectra. In Table 2, we present the known properties for each of the galaxies containing an outburst candidate.

In Fig. 7, we plot the distribution of the apparent magnitudes of all SDSS galaxies with CSS matches along with those containing new CSS outburst candidates. The galaxies with new outburst candidates are clearly peaked at bright magnitudes. This peak coincides directly with that seen in the distribution of SDSS galaxy magnitudes. The strong peak in SDSS galaxy magnitudes is due to the \(r_{P} \leq 17.7\) spectroscopic target selection. Fainter spectroscopically confirmed SDSS galaxies come from the BOSS survey as well as other later generation SDSS surveys. Our selection is clearly not uncovering new outbursts in the fainter galaxies. However, Fig. 7 does show that the hosts with new outburst candidates are generally fainter than those with previously known SN candidates. We believe this is predominately because the nearby bright galaxies are better monitored and the bright SNe that they contain have already been discovered.

The redshift distributions of the 1.4 million matched SDSS galaxies is shown in Fig. 8. Here, we note that the SDSS BOSS galaxies generally have redshifts \(z > 0.2\). Thus, we find that the lack of new outburst candidates in the faint SDSS BOSS galaxies relates to them being generally more distant. This agrees with the idea that most of the new outbursts are due to SNe. That is, SNe in general have peak magnitudes \(M_{V} > −19.3\) (the peak luminosity for type-Ia SNe). At \(z = 0.2\) regular SNe have peaks with \(V > 20.5\). Thus, such events are undetectable in the CSS data. However, superluminous SNe can be much brighter and are detectable to \(z \sim 0.3\).

5.1 Emission line galaxies

SDSS DR13 provides an assessment of the nature of each spectrum by way of an assigned class. This parameter has values of ‘STAR’, ‘QSO’, and ‘GALAXY’, and is determined on the basis of the chi-squared value of the data with respect to a model (Bolton et al. 2012). Galaxies with narrow emission lines are sub-classified into AGNs and star-forming types based upon measurements of [OIII]/H\beta and [NII]/H\alpha line ratios. The resulting subclasses are noted as ‘Star forming’, ‘Starburst’, and ‘AGNs’. An additional separate assessment of ‘Broad line’ is appended for spectra having emission lines with width \(\sigma > 200\) km s\(^{-1}\).

In Table 3, we present the percentage of the total sample for each of the galaxy sub-classes having emission lines. Interestingly, while only \(\sim 16.7\) per cent of the 1.4 million SDSS are classified as star
forming, 47 per cent of the known SNe hosts and 57 per cent of the hosts with newly outbursts are star forming. Higher numbers of CCSNe are expected in star-forming galaxies than passive ones since they are due to massive stars with short lives. In contrast, type-Ia SNe are known to occur in galaxies regardless of recent star formation. Nevertheless, the fact that we observed 3.4 times as many new outburst candidates in star-forming galaxies is larger than expected since our sample is mainly magnitude-limited by the SDSS legacy survey $r_P \leq 17.7$ follow-up limit. For that limit, Li et al. (2011a) show that the number of type-Ia’s far exceeds CCSNe, since type-Ia’s are significantly brighter on average. In contrast, Li et al. (2011a) found that for their volume-limited sample, $\sim$76 per cent of their SNe were core-collapse.

An important difference between our galaxy sample and that of Li et al. (2011a,b), is that the latter may have missed a larger fraction of nearby faint dwarf galaxies since most such galaxies
were uncatalogued at the time their survey began. Thus, it is very unlikely that their volume-limited sample was as complete as ours at the low-mass end. Dwarf galaxies often have very high specific star formation rates (SSFR, Li et al. 2011b, Huang et al. 2012). Furthermore, our selection of candidates from light curves naturally introduces a bias towards detecting outbursts in intrinsically faint galaxies (since the variation in such a galaxy’s light curve will be larger). This effect is balanced slightly by the fact that fainter local galaxies are missing from the SDSS spectroscopic sample because of the magnitude limit. Indeed, dwarf galaxies do not seem to play a significant role since the new outburst hosts generally have \(-18 < M_V < -22\), and are thus as much as \(\sim 5\) magnitudes brighter than the faintest dwarf galaxies where SNe have been discovered (Williams et al. 2008, Drake et al. 2011b).

As a more complete test, we consider the combination of the known and new outburst hosts since many of the SNe in intrinsically bright galaxies were already known. Fig. 9, shows that the host galaxies of the new outbursts are \(\sim 1\) mag less luminous (on average) than those with previously known SN candidates. In the combined known plus new outburst case, we see that 49 per cent of the galaxies are star forming. When we add the starburst host galaxies to the star forming ones we see that \(\sim 60\) per cent of the new outburst plus known SN candidates are in active star-forming galaxies. Thus, overall most of host galaxies with outbursts are undergoing significant star formation.

We also note that the number of new outbursts associated with broad-lined hosts is much lower than those of previous SN candidates. This may suggest that some of the previously discovered and unconfirmed SN candidates were due to AGN activity. It is also
Figure 5. The variability of new outburst candidates and previously known SN candidates. The large green dots show the scatter for galaxies with previously known SN candidates. The red squares are the new outburst sources and the black points are from a random sample of 50,000 SDSS galaxies with spectra.

It is possible that some of the galaxies contain broad lines due to SNe rather than a supermassive black hole (SMBH). Indeed, a number of SNe have already been found within the SDSS spectroscopic galaxy sample (Graur et al. 2015). However, significant contamination seems unlikely since spectra with SN represent $\sim 0.01$ per cent of the SDSS galaxies analysed by Graur et al. (2015).

Although only a small fraction of the new outbursts are associated with hosts that are noted by SDSS as either AGNs or having broad lines, it is worth considering AGNs as a possible source for the new events. In particular, it is possible that a number of AGNs have not been identified due to the weakness of visible narrow lines (Koss et al. 2017).

5.1.1 Active galactic nuclei

AGNs are responsible for the bulk of the optical variability observed in galaxies. Their presence is almost guaranteed when searching for variability within galaxies. However, the nature of AGN variability itself is known to be quite well modelled as a damped random walk process (Kelly, Bechtold & Siemiginowska 2009; MacLeod et al. 2012). Flaring events that appear to be associated with AGNs have only been found in the last decade as samples of hundreds of thousands of AGNs are regularly monitored by transient surveys (MacLeod et al. 2016; Graham et al. 2017). In some cases, these events are believed to be due to phenomena such as microlensing, superluminous SNe, tidal disruption events (e.g. Lawrence et al. 2016), or changes in the accretion or dust environment that might cause an AGN to appear to turn on (e.g. LaMassa et al. 2015; Gezari et al. 2017; Stern et al. 2017).

To understand how many of the newly detected outbursts might be due to AGN variability, we decided to investigate the nature of the host galaxies. The SDSS AGN classifications are based solely on the ratios of [OIII], H$\alpha$, and [NII] lines. Since the selection of AGNs via a single set of criteria is subject to uncertainties and the presence of individual lines and accuracy of their measurements, we decided to calculate the four sets of line ratio diagnostics given by Kewley et al. (2006) for each galaxy with narrow emission lines. The four diagnostic diagrams are presented in Figs 10 and 11 for the hosts of both previously known SN candidates and new outburst candidates. In addition to the lines used by SDSS, these include measurements for [SII], [OIII], and [OII]. Such line diagnostics have been widely adopted for the purpose of AGN classification.

The measurements we use are based on Thomas et al. (2013) and come from SDSS DR13, where they are known as the Portsmouth...
Table 2. Properties of outburst host galaxies.

*Denotes whether a galaxy is an AGN based on the spectrum and/or WISE.

Figure 7. The distribution of apparent V_{CSS} magnitude for SDSS galaxies. The blue-dotted line shows the distribution for the 1.4 million SDSS galaxies with measured redshifts z < 0.5 and CSS photometry. The green-dashed line shows the distribution of redshifts for the 3,340 galaxies with known SN candidates. The red solid line shows the distribution for galaxies with newly discovered outbursts.

Figure 8. The distribution of SDSS galaxy redshifts. The blue-dotted line shows the distribution for the 1.4 million SDSS galaxies with measured redshifts z < 0.5 and CSS photometry. The green-dashed line shows the distribution of redshifts for the 3,340 galaxies with known SN candidates. The red solid line shows the distribution for galaxies with newly discovered outbursts.
As expected, we found very good agreement between the measured fluxes were at least twice their assigned uncertainties. Thus, only \( r < 5 \) per cent in the case of the generally low star formation rates. We see that the hosts of new outbursts have lower mass hosts than the previously known SN candidates and the overall galaxy population. This effect is quite clear that only a small number of the outburst candidates can be attributed to either regular stochastic AGN variability or rare AGN flares. Of course, SNe also occur in galaxies with AGNs. So the fact that a candidate occurs in a host with an AGN does not mean that an outburst is due to an AGN. Indeed, the rate of SNe in galaxies with AGNs is expected to be similar to that in non-AGNs (Cappellaro, Evans & Turatto 1999). Since our sample of outbursting events in AGNs is so small, it is not possible to judge whether the AGNs with broad lines (type-1 AGNs) is different than the rate in type-2’s where the broad lines are obscured. Nevertheless, the presence of AGN variability would certainly increase the threshold required to detect outbursts in AGNs. Thus, SNe are expected to be under-represented in AGNs.

5.1.2 Star-forming galaxies

The rate of CCSNe is expected to be highest in galaxies with active star formation (Petrosian et al. 2005). This clearly is borne out by the very high fraction of new outbursts that we found to be in star-forming galaxies. To better understand this link, we extracted masses and star formation rates for each galaxy with values given by DR13, based on Maraston et al. (2006). This set consists of values for \( \sim 1 \) million of the galaxies in the full sample of SDSS galaxies. Thus, only \( \sim 30 \) per cent of the galaxies in our CSS-SDSS sample do not have star formation measurements.

In addition to star formation rates, the SDSS galaxies also have mass determinations. In order to have reasonable confidence in the mass estimates, which are based on fits to the SDSS spectra, we decided to only include those hosts where the goodness-of-fit value was \( \chi^2 < 1.5 \).

In Fig. 12, we plot the host masses and star formation rates for the full sample of SDSS galaxies as well as those with previously known SN candidates and the new outbursts. Overall, we see that the new outbursts have lower mass hosts than the previously known candidates and the overall galaxy population. This effect is most likely due to the fact that the low-mass hosts are less luminous. Thus, the outbursts can be more easily detected. Additionally, as noted above, many low-mass hosts have high star formation rates.

As expected, most of the galaxies in the full SDSS sample have low star formation rates. We see that the hosts of new outbursts and previously known SN candidates generally have higher rates.
than the full sample. This is consistent with the high fraction of events in star-forming galaxies noted above. These star-forming galaxies tend to have rates of 0.1 to 0.6 $M_\odot$ yr$^{-1}$. Intriguingly, the fraction of galaxies with SFR $> 10 M_\odot$ yr$^{-1}$ is the same for the full SDSS galaxy sample as for the hosts of known SN candidates (~15 per cent). It is not clear if this is a real effect, or inaccurate star formation rates due to the presence of flux from contaminants (such as AGNs).

6 EVENT TIME-SCALES

As noted earlier, the bulk of the new outbursts are almost certainly due to SNe. In cases where a new source is seen offset from the core of a galaxy, this is almost a certainty. However, strong evidence for the SN origin of the events also comes from their time-scales.

For each outburst candidate, we measured the time span over which the event was continuously $>1\sigma$ brighter than the median.
Outbursts

Figure 12. SDSS galaxy properties. The left-hand panel shows the distribution of galaxy masses. The blue-dotted histogram gives the distribution for 1.0 million SDSS galaxies with mass estimates and goodness-of-fit $\chi^2 < 1.5$ from SDSS DR13. The dashed-green line shows the distribution for SDSS hosts with previously known SN candidates. The solid-red line shows the distribution for new outburst candidates. The right-hand panel shows the star formation rates for the same groups of galaxies (using the same colour coding).

Figure 13. Event time-scales. The time span distribution for known SN candidates is plotted with the dashed-green histogram. New outburst candidates are plotted as the solid-red histogram.

Since the outbursts are not very well sampled in general, this provides only a rough estimate for the time-scale for each event.

Fig. 13 shows the distribution of outburst time-scales along with the time-scales for the previously known SN candidates that are present in the CSS photometry. Clearly, the two time-scale distributions are an excellent match, and both are strongly peaked near a time span of 50 d.

In Fig. 14, we show the temporal distribution of event peaks for both previously known SN candidates and new outbursts. This figure shows that the new detections are generally clustered in time (due to the fact that the SDSS fields are only visible for part of the year). It also shows that the rate of SN discovery, in spectroscopically confirmed SDSS galaxies, has increased dramatically in over the past few years.

In general, we expect the true time span of the events to be longer since sparse sampling and observing gaps evident in Fig. 14 often cause the beginning or end of an event to be missed. In addition to the main peak, the time-scale distributions exhibit a second broad feature.

The longest events in the time-scale distributions are inconsistent with those of most common SNe. That is to say, regular SNe typically last for around 100–200 d and have rise times of less than ~40 d. Longer time-scale types of SNe consist of type II-Ps and type IIns. Type II-Ps are often detectable for a couple of hundred days (Li et al. 2011a), while in exceptional cases type-IIns can last for many years (Rest et al. 2011; Fox et al. 2015). However, both type-IIPs and long time-scale IIns have been found to comprise <10 per cent of SNe in the Li et al. (2011a) magnitude-limited SN sample, although II-Ps comprise 40 per cent of SNe in a volume-limited sample (Li et al. 2011a). Note however that some of the outburst time-scales are likely errant due to uncertain start and end times.

In contrast to our outburst candidates, Graham et al. (2017) found 51 large amplitude ($\delta V_{CSS} > 0.5$ mag) outburst events with typical time-scales of 900 d from a sample of 900 000 QSOs. In our analysis we only find a few long time-scale events in our sample of 1.4 million galaxies. This strongly suggests a real difference in the number of long time-scale events between normal galaxies and AGNs, since only ~3 per cent of our input galaxy sample are known AGNs. Nevertheless, it is worth considering how other selection effects might have caused a difference in the observed time-scales.

For the bulk of events that occur in galaxies that lacking evidence for an AGN, it is unlikely that our selection process misses events lasting hundreds of days with amplitudes >0.5 mag. This is because the scatter in the light curves is generally <0.5 mag and most light curves span more than 3000 d. However, events lasting a few
thousand days could be missed since the event itself would increase
the photometric scatter and thus in increase the detection threshold.
In the case of AGNs, events could also be missed due to the increased
scatter from intrinsic variability. Searches based on light curve fits,
such as carried out in Graham et al. (2017), are preferable for such
sources.

7 MLS SOURCES

Of the ∼1.7 million SDSS DR13 galaxies with spectra and z < 0.5,
∼380,000 overlap with the Catalina MLS survey. Since MLS has a
much smaller field of view than CSS, the coverage is sparse away
from the ecliptic. Only about half (152,000) of the matches between
MLS and SDSS have 20 or more nights of observations. Thus, the
full sample of MLS-SDSS matches is only ∼10 per cent that of the
CSS set.

Applying the same selection criteria as with the CSS data, we
found 561 initial candidates. After inspecting the light curves, and
removing the previously known SNe candidates, this number is sig-
nificantly reduced to just 70 candidates. We then inspected 400 im-
age cutouts associated with the peaks detected for these candidates.
This reduced the number of MLS outburst candidates to just 38.

The MLS data has much better resolution than CSS data since
the original camera had 1 arcsec pixels (compared to 2.5 arcsec).
For 13 of the 38 outburst candidates, we noted the presence of new
source offset from the core of the host galaxy in the MLS images.
These events are all likely to be SNe. Of the 38 candidates, 12 had
already been found in our analysis of the CSS data. The remaining
25 new MLS candidates are presented in Table 4.

Since the CSS survey covers all of the area of MLS, we extracted
and inspected the CSS light curves for each of the MLS outburst
candidates. Among the 25 new MLS outbursts, 16 showed some
brightening in CSS data taken during the event. Thus, these 16
events are all considered to be very strong outburst candidates. The
other MLS candidates generally lacked good CSS coverage during
the events.

As with CSS candidates, we extracted the light curves of all of
the previously known SNe candidates in the MLS-SDSS sample.
Inspecting the MLS light curves, we found five events that were
visible in the MLS data, yet missed initial selection due to low
significance. Five more were missed since their light curves actually
exhibited a decrease in flux during the outburst. This decrease is due
to the aperture of the SN sequestering some of the host galaxy’s flux
when it is detected as a separate source offset from the host.

Comparison of the rate of new outbursts per galaxy for the MLS
data and CSS data shows that the rate for MLS is only half that of
CSS. This difference is due to two factors. First, the MLS data has
far fewer observations per object on average than CSS. Specifically,
during our analysis period the MLS dataset has an average of 43
nights of observations per galaxy, while CSS has 99. Secondly, the
MLS has higher resolution and better average observed seeing than
in CSS. Thus, any SNe that are offset from their hosts are more
likely to be detected as a new source in MLS data than in CSS
data. This means that the MLS galaxy light curves are less likely to
include the flux of an offset SNe.

8 EVENTS OF INTEREST

8.1 CRTS.OBC_204

Although almost all of the new outbursts detected in CSS and
MLS are likely to be regular SNe, there are a few that clearly
are not. One of the unusual events we discovered in our analysis
is CRTS.OBC_204, occurring in the confirmed AGN containing
galaxy SDSS J233454.07 + 145712.8.

The light curve for this galaxy is presented in Fig. 15. The source
exhibits a very strong outburst that appears to have taken ∼60 d
to reach a peak of $M_V = -21.1$ (after subtracting flux from the
galaxy) in 2009 mid-December. Overall, this event appears to have
lasted at least 1700 rest-frame days. The shape of the light curve is
consistent with that of any known type of SN. However, the peak
brightness is consistent with superluminous SNe. The host for this event is clearly extended in SDSS images.

A low signal-to-noise ratio (∼3.5σ) radio source is seen in the NVSS survey (Condon et al. 1998) at the location of the host. However, the flux appears extended and the source does not appear in the NVSS catalogue. This suggests that the flux may simply be due to noise. Furthermore, no radio source is seen in VLSS (Perley et al. 2007) or TGSS survey data (Intema et al. 2017).

The light curve of CRTS_OBC_204 is similar to that of CRTS transient CSS120103:002748-055559, which was noted by Breedt et al. (2012) as being due to a blazar at $z = 0.428$. However, Breedt et al. (2012) based their blazar classification on the detection of broad lines and a radio detection in NVSS data. Our own analysis of NVSS data suggests that the significance of the radio detection is <2σ. Furthermore, CSS120103:002748-055559 does not appear in deeper FIRST survey radio data (Becker, White & Helfand 1995), nor in TGSS or VLSS radio data. We suggest that neither CRTS_OBC_204 nor CSS120103:002748-055559, are blazar outbursts. Rather they are flares from radio-quiet QSOs. The light curve of CRTS_OBC_204 also resembles the QSO flares found by Graham et al. (2017).

We obtained follow-up spectra of CRTS_OBC_204 with the Palomar 5m and Double Beam Spectrograph (DBSP) on UT 2017 July 27 and 2017 August 29. The new spectra were not significantly different from the original SDSS spectrum. However, since our spectra were both taken many years after the peak of the event, when the source appears to have returned to quiescence, this is not unexpected.

While this paper was in preparation CRTS_OBC_204 was identified as a potential AGN flare by Kankare et al. (2017) based on the shorter light curves available in our public CSDR2 release.

### 8.2 CRTS_OBC_62

In Fig. 16, we present the light curve of the long-time-scale outburst candidate CRTS_OBC_62 ($\alpha = 15:45:43.55, \delta = 08:58:01.3$ J2000). This event was found in known Lyman alpha emitting blue dwarf galaxy 1543 + 091 (Meier & Terlevich 1981). As with CRTS_OBC_204, after peak this event initially fades and then rises again slightly to form a plateau that lasts for hundreds of days.

Interestingly, Izotov, Thuan & Prion (2012) noted that the host galaxy displays the presence of [FeV]4227 and [NeV]3426 which they...
attribute to hard ionizing radiation. They also note that, although
the spectrum shows the presence of [He II]4686, it lacks the bump
signature associated with Wolf–Reyet (WR) stars. They suggest that
the source of the hard radiation is either an AGN or fast radiative
shocks, such as caused by SNe.

Sartori et al. (2015) selected this galaxy as a very rare (< 1 per cent of their 50 000 galaxy sample) example of an AGN in
a low mass galaxy (log(M⊙) = 8.2) based on mid-IR data. How-
ever, Senchyna et al. (2017) suggest that such hard-ionizing spectral
features with the lack of a WR bump are consistent with massive O-
stars in a low metallicity environment (as is observed in 1543 + 091).

8.3 Other interesting events

A number of the new outburst candidates in this analysis were found
in the same hosts as previously known SN candidates. For example,
CRTS_OBC_9 is a long event that occurred in 2007 and resides
in the same galaxy that hosted SN candidate AT2016gbz. Like-
wise, CRTS_OBC_324 occurred in the galaxy that hosted AT2017io.
CRTS_OBC_331 occurred in the same galaxy as SN 1955Q, and
CRTS_OBC_127 occurred in the galaxy that hosted SN 2017me.

The occurrence of multiple SN within the same host is not
expected since there are many examples of active SN hosts. For
example, five SNe were detected in NGC 309 over the span of
15 yr.7

One of the more interesting outburst candidates is
CRTS_OBC_216 (Fig. 17). This event occurred in the same host
galaxy as known SN 2010ay. SN 2010ay was a rare broad line
type-Ic SN discovered by CRTS (Drake et al. 2010). Such SN have
long been known to be associated with long time-scale gamma-ray
bursts (GRBs; Galama et al. 1998). In this case, the host galaxy has
low metallicity and exhibits rapid star formation. These features
have also been observed for many GRB-associated SN (Modjaz
et al. 2010). However, SN 2010ay was noteworthy for lacking any
radio or gamma-ray emission (Sanders et al. 2012). The CSS light
curve shows that SN 2010ay is seen to peak in CSS data around
UT 2010 March 17, while CRTS_OBC_216 occurred just 2 yr later.

Surprisingly, this second event was not noted by transient surveys
or groups performing follow-up of SN 2010ay.

Inspection of the SDSS images for this galaxy shows minimal
extension. The locations of the two events are not resolved from
each other, nor from the core of the host in CSS images. Thus, it is
not clear whether or not the two events are related.

8.3 Other interesting events

9 DISCUSSION

9.1 SNe as a source of outbursts

The new outburst candidates that we have identified are predominantly consistent with SNe based on their light-curve shapes and time-scales. In some cases this is confirmed by the presence of a new source within the images. The host galaxies of the outburst candidates are predominantly star-forming galaxies. This latter feature also matches the hosts of most previously discovered SN candidates in this same sample. Very few of the new outbursts are detected in galaxies with known AGNs, suggesting few are likely to be associated with variable black hole accretion.

In comparison to this work, Graur et al. (2015) found 91 SN in the SDSS spectra of 740,000 galaxies. Among their detections only 23 SN were new discoveries. Additionally, Drake et al. (2014) serendipitously discovered 42 likely SNe from light curves while searching for periodic variables in CSS data. Of those, only six were in galaxies having SDSS spectra. Assuming that the fraction new SNe in galaxies from Drake et al. (2014) is representative of the fraction of the full sample, we expect that there should be roughly six times as many outbursts (~4200) in CSS galaxies photometry without SDSS spectra. This number is close to the total number of SN candidates that have been discovered by CRTS. Thus, a very large number of additional outbursts should be present within the CSS data. Additionally, it is likely that the number of detections could be increased by using image subtraction.

Considering what could be learnt from our new outburst candidates, we note that Kelly & Kirshner (2012) studied a sample of could be increased by using image subtraction.

9.2 AGN as an outburst source

In our current analysis, we specifically chose an outburst search technique that was model-free in order to minimize assumptions about the form the outbursts might take. In comparison to recent outbursts found in the Catalina light curves of QSOs (Graham et al. 2017), the hosts of our outbursts generally do not exhibit underlying variability. This makes the interpretation of our outbursts clearer than in the case of those with AGN. Furthermore, this enables us to use a much lower effective detection threshold than Graham et al. (2017), or the searches of Lawrence et al. (2016) and Kankare et al. (2017).

With this in mind, it is interesting to note that we only find evidence for large-amplitude long-time-scale flares in a small number of galaxies that clearly include AGNs. The general lack of such events in quiescent galaxies strongly suggests that the events that have been found in AGNs are in some way associated with the presence of a SMBH and associated accretion disk. Nevertheless, we cannot strongly constrain whether the AGN-related events in Lawrence et al. (2016) and Graham et al. (2017) are in fact lensed by sources in foreground galaxies. The results do suggest that, if the flares seen in AGNs are associated with luminous SNe, as suggested for CSS100217 (Drake et al. 2011a) and PS16dtm (Blanchard et al. 2017) which both reside in NLS1 galaxies, they could well be associated with the black hole accretion disc.

9.3 TDEs as an outburst source

With the large number of new outburst candidates, it is worth considering the possibility that some of the events are associated with TDEs. TDEs were originally predicted to characteristically decline with time as $M(t) \propto t^{5/3}$ (Evans & Kochanek 1989). However, more recently, widely varying estimates of the decline rate have been suggested (for example, see Lodato & Rossi 2011). The current data for TDE candidates show that they do indeed exhibit a wide range of decline time-scales (Auchettl et al. 2017). Thus, the sparsely sampled CSS light curves are far from ideal for separating TDEs with poorly constrained decline rates from SNe that are also well known to have diverse decline rates.

Considering other methods for identifying TDEs, Hung et al. (2017) recently undertook an analysis of iPTF data observed as part of their TDE search. In their work, they suggested that high-precision astrometry is essential for finding TDEs, their reasoning being that type-Ia SNe have similar colours and are far more common than TDEs (even within the cores of galaxies, i.e. $<0.8$ arcsec from the centre). However, we note that a truly definitive separation requires optical spectra and ideally an X-ray signature. The spectroscopic signature of TDEs is predominately considered to be the presence of strong, broad helium lines (Gezari et al. 2012).

In their survey, Hung et al. (2017) required outbursts reaching a threshold of $\Delta M > 0.5$ mag. This is a higher threshold than many of the events we have found in this analysis. We note that both our work and the Hung et al. (2017) TDE survey are necessarily biased against the discovery of events in intrinsically bright galaxies.

Unlike our current analysis, Hung et al. (2017) concentrated their analysis solely on red galaxies. They reasoned that most known TDEs have so far been found is such galaxies. However, it seems likely that this is at least partly due to the fact that prior searches included a strong selection bias against other types of galaxies. That is to say, like SN surveys, many past searches for TDEs specifically avoid galaxies where an AGN might be present due to the difficulty of disentangling the signature of a TDE from an AGN. Thus galaxies with blue continua (due to the presence of AGNs or star formation), are under represented in the search samples. Indeed, Blanchard et al. (2017) suggest that AGN flares may be due to TDEs, and that these may be more common in AGN than previously believed. In
addition, Tadhunter et al. (2017) suggest that the rate of TDEs in ultra-luminous infrared galaxies may be much higher than in normal galaxies. Indeed, the numerous flaring events that have recently been found within AGNs (e.g. Drake et al. 2011a,b; Lawrence et al. 2016; Blanchard et al. 2017; Graham et al. 2017) appear to be roughly consistent with a TDE origin. On the other hand, Lawrence et al. (2016) suggests, the amount of energy released by a TDE is far less than seen in many of the observed AGN flaring events.

Overall, it is possible that some of the new outbursts are due to TDEs. In particular, CRTS_OBC_204 is clearly not a regular SN, and occurred within a host containing an AGN. However, since predicted TDE rates are so much lower than SN rates, we do not expect many of the outbursts to be due to TDEs.

9.4 Considerations for the future

As we look forward to larger transient surveys that are coming (such as ZTF and LSST), we expect an ever growing number of transient discoveries. As with current surveys, a very large fraction of the transients will undoubtedly be SNe. It is therefore worth considering what may be learnt from such objects when there are already far more SN being discovered than can be spectroscopically confirmed.

In Fig. 18, we plot the number of discovered SN candidates and the number of confirmed SN over the past 22 yr. Encouragingly, this figure shows that the amount of SN follow-up has increased at an approximately linear rate over this time. However, in contrast, the SN candidate discovery rate appears well modelled by an exponential increase in addition to the linear confirmation-rate trend.

Examining the SN confirmation data, we find that the shortfall in SN confirmation is highly magnitude dependent. Specifically, based on historical SN data, only 10–20 per cent of the SN discovered since 1950 with \(20 < V < 22\) have been spectroscopically confirmed, while roughly 80 per cent of SN candidates brighter than \(V = 17\) have been spectroscopically confirmed.

In the near term, surveys such as ZTF and LSST will almost certainly increase the SN discovery trend by introducing many more transients with luminosities that have not been historically followed. The very faint events discovered by LSST will be particularly difficult to confirm spectroscopically. Characterization will be further hindered by the fact that LSST light curves will not be as well sampled as many existing transient surveys. For brighter events, it is possible to mitigate the follow-up problem to some extent by using historical information. However, a better understanding of fainter events should also make use of the data for the tens of thousands of brighter transients that have been already been found by existing transient surveys. These should be used to glean a fuller understanding of the event parameter space.

As new transients are discovered in future surveys, the existence of better sampled light curves and colour information (in the case of ZTF), combined with accurate astrometry (from Gaia), will undoubtedly aid our ability to classify optical transients. Nevertheless, a significant amount of additional characterization work is required now since spectroscopic follow-up resources are unlikely to have a significant impact on the overall fraction of characterized events. Classification and follow-up also remain crucial for determining the nature of long time-scale AGN-associated events as well as other very rare types of transients such as GW170817 (Abbott et al. 2017) and 2018cow (Perley et al. 2018).

10 SUMMARY

In this work, we have taken a step towards understanding the types of extragalactic transients that were missed by existing transient surveys. We used light curves from the Catalina Surveys to find them, and archival spectra to help characterize their hosts.

The main discovery of this work has been the discovery of more than 700 new outbursts among more than 1.4 million spectroscopically confirmed SDSS galaxies. As expected, we find that most of these events are consistent with SNe. However, we cannot exclude the presence of rare transient types since specific classifications are only possible for a small number of the sources. Nevertheless, we find a small number of long time-scale events that are associated with galaxies containing AGNs. These outbursts appear relatively consistent with the events discovered in AGN-containing galaxies by Lawrence et al. (2016) and Graham et al. (2017). Importantly, we do not find these long time-scale events among the >95 per cent of galaxies in our sample that lack a significant evidence of AGNs. This strongly suggests that the long time-scale events are in some way associated with AGNs. As yet we are unable to determine whether the source of the long outbursts are intrinsic to AGNs or their environment, or are due to an extrinsic effect such as microlensing of the AGN.

ACKNOWLEDGEMENTS
