I. INTRODUCTION

After their first experimental realization [1, 2] in 1995, Bose-Einstein condensates (BECs) in ultra-cold atomic vapor are now routinely created and manipulated in many laboratories. Since then, experimentalists have gained a significantly higher level of control over BECs through technological and methodological advancements, including low-temperature records in the sub-nK regime [3], creation and manipulation on an atom-chip [4, 5], and sending BECs to space [6], allowing fundamental research in a microgravity environment.

In state-of-the-art technology, BECs are used for high precision measurements of forces [7, 12] by means of matter-wave interferometry, where the wave function of each atom is split into two wave packets that are sent on different paths and then brought into interference.

For optical interferometry, it is well known that one may enhance the sensitivity by employing non-classical (e.g., squeezed) states, which has been successfully implemented in the gravitational wave detectors of the LIGO-Virgo collaboration [13–15], for example. More generally, quantum metrology refers to the exploitation of quantum properties (such as entanglement) in order to gain significantly higher sensitivities for measurement technologies [16]. Quantum enhanced sensing has also been proposed for matter-wave interferometry [17] and other sensing applications of cold atomic systems [18].

For cold atoms however, the strict conservation of their total number poses restrictions on the available phase space of quantum superpositions. Thus, it might be advantageous to employ the quantum states of collective oscillations such as phonon modes in the BEC.

First studies of collective oscillations in BECs were already performed in early experiments [19–21]. Highly excited quasi-particle states can be created with light pulses [22] and periodic modulations of the trap potential [23, 24]. Measurement methods include self-interference of the Bose gas after release from the trap denoted as heterodyning [22] or time-of-flight measurements and in-situ phase contrast imaging [21, 25]. A specific example of the utilization of collective oscillations in BECs for sensing was the measurement of the thermal Casimir-Polder force presented in [26–27].

Exploring the potential of BECs for sensing applications further, it has been proposed to use collective oscillations in BECs to measure the effect of space-time curvature on entanglement [28–30], for high-precision gravity sensing [31–32], for detecting gravitational waves [33–37] and for testing gravitationally induced collapse models [38].

In order to detect extremely small effects (such as the gravitational phenomena mentioned above), many proposals for sensing with collective oscillations in BECs rely on elements of quantum sensing employing specific quantum states. However, these highly non-classical (e.g., squeezed) states are typically also quite prone to noise and decoherence [18, 39]. In this work, we study the effects of decoherence caused by the omnipresent process of three-body loss in BECs. In contrast to other decoherence channels such as Landau or Beliaev damping (see, e.g., [40]), this mechanism is not suppressed when going to ultra-low temperatures (as for Landau damping) or energies (as for Beliaev damping).

II. THREE-BODY LOSS

Bose-Einstein condensates of ultra-cold atomic vapor are not the true ground states, which would be solid. They are meta-stable states which can be rather long lived because two atoms alone cannot bind and form a molecule as energy and momentum conservation forbid them to dispose of the released binding energy. However, if a third atom is close by (i.e., within the short interaction range) and carries away the excess energy and momentum, this recombination process can occur. Since the energy scales (set by the binding energy) are typically much larger than the characteristic energy scales of the ultra-cold BEC, effectively all three atoms are lost from the BEC in such a process.

(Dated: October 4, 2021)

In view of the coherent properties of a large number of atoms, Bose-Einstein Condensates (BECs) have a high potential for sensing applications. Several proposals have been put forward to use collective excitations such as phonons in BECs for quantum enhanced sensing in quantum metrology. However, the associated highly non-classical states tend to be very vulnerable to decoherence. In this article, we investigate the effect of decoherence due to the omnipresent process of three-body loss in BECs. We find strong restrictions for a wide range of parameters and we discuss possibilities to limit these restrictions.
associated length (interaction range) and time scales are much shorter than those of a BEC, such that one may approximate the recombination process as local in space and time. Thus, we use the Born-Markov approximation and describe these three-body loss processes via a Lindblad master equation \((h = 1)\), see also [11]
\[
\frac{d\hat{\rho}}{dt} = -i \left[ \hat{H}_0, \hat{\rho} \right] + \Gamma \int d^3r \left\{ \hat{\psi}^\dagger(r) \hat{\psi}(r) \hat{\rho} \right\} + \frac{\Gamma}{2} \int d^3r \left\{ \left[ \hat{\psi}^\dagger(r) \right]^3 \hat{\psi}(r), \hat{\rho} \right\} .
\] (1)

Here \(\hat{H}_0\) is the usual Hamiltonian governing the undisturbed dynamics of the BEC and \(\hat{\rho}\) denotes its density matrix. The Lindblad jump operators are given by third powers of the field operators \(\hat{\psi}(r)\) in second quantization, each one corresponding to the annihilation of an atom at position \(r\). Finally, \(\Gamma\) is the bare loss rate.

In order to clearly distinguish different effects, we assume scale separation, i.e., the characteristic length scales (e.g., size) of the condensate are supposed to be much larger than the wavelengths of the phonon modes under consideration — which, in turn, should be much longer than the typical length scales of the atomic interactions and the three-body losses.

A. Mean-field approximation

As usual, we split the atomic field operator \(\hat{\Psi}(r)\) into the macroscopically occupied mode \(\hat{a}_0\) described by the condensate wave-function \(\psi_c(r)\) plus the field operator \(\hat{\chi}(r)\) for all other modes
\[
\hat{\Psi}(r) \approx \psi_c(r)\hat{a}_0 + \hat{\chi}(r).
\] (2)

This is followed by the Bogoliubov approximation, where the field \(\hat{\chi}(r)\) is treated as a small perturbation (in view of the large occupation of the condensate mode).

Inserting split (2) into the Lindblad equation (1), the zeroth order in \(\hat{\chi}(r)\) yields the decay of expectation value of the number of atoms in the condensate
\[
\frac{dN_c}{dt} = \frac{d}{dt} \langle \hat{a}_0^\dagger \hat{a}_0 \rangle \approx -3\Gamma \int d^3r |\psi_c(r)|^6 \langle (\hat{a}_0^\dagger \hat{a}_0) \rangle
\approx -3\Gamma N_c^2 \int d^3r |\psi_c(r)|^6 ,
\] (3)

where we have used the standard approximation of the condensate as a coherent state in the last step. This can be reformulated in terms of the condensate density \(\rho_c(r) = N_c |\psi_c(r)|^2\) which then leads to
\[
\frac{d}{dt} N_c = \frac{d}{dt} \int d^3r \rho_c(r) \approx -3D \int d^3r \rho_c^3(r) ,
\] (4)

where \(D = 3\Gamma\). This is the usual equation describing three-body loss in BECs with decay constant \(D\) (see, e.g., Section 5.4 of [22] and in [33, 34]). For example, based on experiments with rubidium atoms, the corresponding decay constant was given as \(D \sim 1.8 \times 10^{-29} \text{cm}^6\text{s}^{-1}\) in [33] and \(D \sim 5.8 \times 10^{-30} \text{cm}^6\text{s}^{-1}\) in [46] for different internal states of the atoms. In the following, we use the second result \(D \sim 5.8 \times 10^{-30} \text{cm}^6\text{s}^{-1}\) when we give numerical values for rubidium BECs. In an experiment [17] with ytterbium, a decay constant of \(D \sim 4 \times 10^{-30} \text{cm}^6\text{s}^{-1}\) was found.

As one may infer from the above equation (4), three-body losses can be quite rare events in very dilute BECs, explaining the comparably long life-time of these metastable states. Still, they are always present and will have profound consequences. As we shall find below, the decoherence induced by three-body losses limits the accuracy of quantum enhanced sensing already on time scales much shorter than the life-time of the condensate. On such short time scales, the depletion of the BEC according to Eq. (4) can be neglected, i.e., \(N_c \approx \text{const}\), and we use this approximation in the following.

B. Phonon modes

The next-to-leading-order terms in \(\hat{\chi}(r)\) describe the dynamics of the state \(\hat{\rho}_\chi\) of the Bogoliubov quasi-particle excitations (see also [33])
\[
\frac{d\hat{\rho}_\chi}{dt} = -i \left[ \hat{H}_0, \hat{\rho}_\chi \right] + 9\Gamma N_c^2 \int d^3r |\psi_c(r)|^4 \times \left( \hat{\chi}(r)\hat{\rho}_\chi \hat{\chi}^\dagger(r) - \frac{1}{2} \left\{ \hat{\chi}^\dagger(r)\hat{\chi}(r), \hat{\rho}_\chi \right\} \right) .
\] (5)

If the Hamiltonian \(\hat{H}_0\) is bi-linear in the field operators \(\hat{\chi}(r)\) and \(\hat{\chi}^\dagger(r)\), this master equation preserves Gaussianity, i.e., maps initial Gaussian states \(\hat{\rho}_\chi\) to final Gaussian states. This will become important later on, but at this point we do not restrict our considerations to Gaussian states.

Note that \(\hat{\chi}^\dagger(r)\) and \(\hat{\chi}(r)\) are not directly the creation and annihilation operators for the quasi-particle excitations, they are related via a Bogoliubov transformation
\[
\hat{\chi}(r) = \sum_{IJ} \hat{a}_I \hat{\phi}_I = \sum_{IJ} \left( u_I(r) \hat{b}_I + v_I^*(r) \hat{b}_I^\dagger \right) .
\] (6)

Here \(\hat{a}_I\) are the original atomic annihilation operators for the modes \(\hat{\phi}_I(r)\) orthogonal to the condensate wave-function \(\psi_c(r)\) while \(\hat{b}_I^\dagger\) and \(\hat{b}_I\) are the quasi-particle creation and annihilation operators, respectively. The mode functions \(u_I\) and \(v_I\) fulfill the stationary Bogoliubov-de Gennes equations and are orthogonalized as
\[
\int d^3r \left[ u_I^*(r)u_J(r) - v_I^*(r)v_J(r) \right] = \delta_{IJ} .
\] (7)

As a result, the master equation (5) contains Lindblad operators \(\hat{b}_I^\dagger\) corresponding to cooling \(\propto u_I\) as well as Lindblad operators \(\hat{b}_I\) describing heating \(\propto v_I\), see also [33]. The perhaps somewhat surprising effect of heating (even at zero temperature) can intuitively be understood in the following way: Due to the small but finite interaction between the atoms, not all of them are in the
III. DECOHERENCE

Now we are in the position to derive the decoherence of the phonon modes due to three-body loss. Of course, to actually solve the master equation \( \hat{H}_0 \), we have to specify the undisturbed Hamiltonian \( \hat{H}_0 \). In the following, we discuss several examples.

A. Pure decay channel

As our first and most simple example, let us omit the undisturbed Hamiltonian \( \hat{H}_0 \) altogether. As a further simplification, we focus on the decay channel, i.e., we only keep the Lindblad operators \( \hat{b}_I \) and neglect all contributions \( \propto v_I \). This will be a good approximation for quasi-particles with wavelengths far below the healing length \( \xi = 1/\sqrt{8\pi a_s \rho_c} \) where \( a_s \) is the s-wave scattering length. In this limit, we get the simple equation

\[
\frac{d\hat{x}}{dt} = \sum_I \gamma_I \left( \hat{b}_I \hat{\phi}_X \hat{\phi}_X^\dagger - \frac{1}{2} \{ \hat{b}_I, \hat{\phi}_X \} \right),
\]

with the mode-dependent decay rates

\[
\gamma_I = 9\Gamma N_c^2 \int d^3r |\psi_c(r)|^4 |u_I(r)|^2.
\]

For quantum enhanced sensing, interesting observables are the quadratures, e.g., the positions \( \hat{X}_I = \hat{b}_I^\dagger + \hat{b}_I \) (note that this quantity is often defined with a factor of \( 1/\sqrt{2} \)). According to Eq. (8), their variances evolve as

\[
\frac{d}{dt} \langle \hat{X}_I^2 \rangle = -\gamma_I \langle \hat{X}_I^2 \rangle + \gamma_I.
\]

In addition to the usual decay term \(-\gamma_I \langle \hat{X}_I^2 \rangle\), we get a noise term \(+\gamma_I\) stemming from the unavoidable quantum fluctuations encoded in the commutator of \( \hat{b}_I^\dagger \) and \( \hat{b}_I \), as expected from the fluctuation-dissipation theorem.

Now, for sensing applications which can be translated to measuring the generalized position variable \( \hat{X}_I \) to high accuracy, a popular scheme of quantum enhanced sensing is to prepare a squeezed state with reduced uncertainty \( \langle \hat{X}_I^2 \rangle_{\text{in}} \ll 1 \) in that direction\(^1\) as the initial state. Then Eq. (10) implies that the variance \( \langle \hat{X}_I^2 \rangle \) is doubled after a relatively short time \( t \approx \langle \hat{X}_I^2 \rangle_{\text{in}} / \gamma_I \). In other words, we find a comparatively fast deterioration of accuracy, which limits the maximum sensitivity: The higher the desired accuracy, the more squeezing is necessary, and thus the faster its deterioration.

B. Squeezing versus decay

Having found such a comparable fast smearing out of the initially narrow variance \( \langle \hat{X}_I^2 \rangle_{\text{in}} \ll 1 \), one could try to counteract this process by continuously squeezing the state in order to reduce \( \langle \hat{X}_I^2 \rangle \) or keep it small. Thus, let us consider the Hamiltonian

\[
\hat{H}_0^S = -i \sum_I \frac{\Xi_I}{2} \left[ (\hat{b}_I^\dagger)^2 - \hat{b}_I^2 \right]
\]

generating single-mode squeezing for all modes \( I \) with the rates \( \Xi_I \). The resulting master equation

\[
\frac{d\hat{x}}{dt} = -i \left( \hat{H}_0^S, \hat{x} \right) + \sum_I \gamma_I \left( \hat{b}_I \hat{\phi}_X \hat{\phi}_X^\dagger - \frac{1}{2} \{ \hat{b}_I, \hat{\phi}_X \} \right),
\]

can be solved for each mode \( I \) independently. The variances can be obtained easily (see also \( 10 \) \( 50 \))

\[
\frac{d}{dt} \langle \hat{X}_I^2 \rangle = -(2\Xi_I + \gamma_I) \langle \hat{X}_I^2 \rangle + \gamma_I.
\]

We see that maintaining small variances \( \langle \hat{X}_I^2 \rangle \ll 1 \) requires rather strong squeezing

\[
\Xi_I \approx \frac{\gamma_I}{2 \langle \hat{X}_I^2 \rangle}.
\]

These strong squeezing rates must be realized experimentally by externally driving the system, which poses restrictions on the potential of quantum enhanced sensing. As another point, such a strong squeezing would decrease one variance \( \langle \hat{X}_I^2 \rangle \) but increase the other \( \langle \hat{P}_I^2 \rangle \) and thus generate excitations.

C. Rotating-wave approximation

Let us now venture a few steps towards a more realistic description of phonon modes, especially those with wavelengths larger or comparable to the healing length. To this end, we include the undisturbed (Bogoliubov-de Gennes) Hamiltonian of the phonon modes

\[
\hat{H}_0^R = \sum_I \omega_I \hat{b}_I^\dagger \hat{b}_I,
\]

with the phonon-mode eigen-frequencies \( \omega_I \), and include the previously omitted terms \( \propto v_I \). Assuming that the phononic frequency scales \( \omega_I \pm \omega_J \) are much faster than

\[1\] Of course, the uncertainty in the other direction \( \langle \hat{P}_I^2 \rangle_{\text{in}} \gg 1 \) would be correspondingly larger.
the Lindblad dynamics, we may use the rotating-wave approximation and arrive at
\[
\frac{d\hat{\phi}_k}{dt} = -i\left[\hat{H}_0^R, \hat{\phi}_k\right] + \sum I \gamma_I^f \left(\hat{b}_I \hat{\phi}_k \hat{b}_I^\dagger - \frac{1}{2} \left\{\hat{b}_I \hat{b}_I^\dagger, \hat{\phi}_k\right\}\right) + \sum I \gamma_I^c \left(\hat{b}_I^\dagger \hat{\phi}_k \hat{b}_I - \frac{1}{2} \left\{\hat{b}_I^\dagger \hat{b}_I, \hat{\phi}_k\right\}\right),
\]
(16)
where the cooling and heating terms are
\[
\gamma_I^c = 9\Gamma N_c^2 \int d^3r |\psi_c(r)|^4 |u_I(r)|^2,
\]
(17)
\[
\gamma_I^f = 9\Gamma N_c^2 \int d^3r |\psi_f(r)|^4 |u_I(r)|^2.
\]
(18)
Consistent with the rotating-wave approximation, we consider the co-rotating-wave quadrature of a single mode $X_I(t) = \hat{b}_I^\dagger e^{-i\omega_I t} + \hat{b}_I e^{i\omega_I t}$, whose variance evolves as
\[
\frac{d}{dt} \langle X_I^2(t) \rangle = -\gamma_I^c \langle X_I^2(t) \rangle + \gamma_I^f,
\]
(19)
where $\gamma_I^c = \gamma_I^f + \gamma_I^f$. Consequently, the conclusions are qualitatively the same as in the previous scenarios. As a main difference, the cooling $\gamma_I^c$ and heating $\gamma_I^f$ terms both contribute equally to the noise $\gamma_I^f$ while they act against each other for the decay rate $\gamma_I^c$.

### D. Homogeneous condensates

In order to obtain more explicit expressions, we have to specify the condensate wave-function. In the following, we assume an approximately homogeneous condensate. Without loss of generality, we set the total chemical potential to zero such that the condensate wave-function becomes (approximately) spatially and temporally constant $\psi_c \approx \text{const}$. In this case, the modes $I$ can be labeled by their wave-numbers $k$ and the frequencies
\[
\omega_k = \frac{|k|}{2m} \sqrt{\frac{2}{\xi} + k^2} = c_s |k| \sqrt{1 + \frac{2}{\xi} k^2},
\]
(20)
Again $\xi = 1/\sqrt{8\pi a_s \rho_c}$ is the healing length, which can also be written as $\xi = 1/\sqrt{2mg \rho_c}$ in terms of the coupling constant $g = 4\pi a_s/m$ of the condensate atoms. Furthermore, $c_s$ denotes the speed of sound given by $1/c_s = \sqrt{2m\xi}$ or $c_s = \sqrt{4\rho_c/m}$.

Apart from the quantization volume normalization, the mode functions $\psi_k$ and $\psi_\kappa$ are given by plane (propagating or standing) waves with the Bogoliubov coefficients $\alpha_k$ and $\beta_k$ as pre-factors, where $\alpha_k = (\sigma_k^{-1} + \sigma_k)/2$ and $\beta_k = (\sigma_k^{-1} - \sigma_k)/2$ with
\[
\sigma_k = \sqrt{1 + \frac{2}{\xi^2 k^2}}.
\]
(21)
The damping constants (17)-(18) reduce to $\gamma_k = \alpha_k^2 \gamma$ and $\gamma_k = \beta_k^2 \gamma$, respectively, where $\gamma = 3D \rho_c^2$, which implies $\gamma_k = (\alpha_k^2 - \beta_k^2) \gamma$ and $\gamma_k = (\alpha_k^2 + \beta_k^2) \gamma \geq \gamma$.

For large $|k| \gg 1/\xi$, i.e., in the free-particle limit $\omega_k \to k^2/(2m)$, we find $\alpha_k \to 1$ and $\beta_k \to 0$ as indicated above and $\gamma_k \to \gamma$. Instead for small $|k| \ll 1/\xi$, i.e., in the phonon limit $\omega_k \to e_k |k|$, both $\alpha_k$ and $\beta_k$ grow as $\sqrt{2}/(4\xi |k|)$. This leads to $\gamma_k \to \gamma/(\sqrt{2k^2})^{-1}$, and the noise term is significantly amplified.

### E. Squeezed reference frame

Actually, one may understand the underlying dynamics even without invoking the rotating-wave approximation employed in Sec. III. Considering a homogeneous condensate, we may use the Fourier expansion of $\hat{\chi}$ as our mode decomposition in equation (6). Inserting this into the master equation (5), we get
\[
\frac{d\hat{\phi}_k}{dt} = -i\left[\hat{H}_0, \hat{\phi}_k\right] + \gamma \sum \hat{a}_k \hat{\phi}_k \hat{a}_k^\dagger - \frac{1}{2} \left\{\hat{a}_k \hat{a}_k^\dagger, \hat{\phi}_k\right\},
\]
(22)
in terms of the original atomic creation and annihilation operators $\hat{a}_k$ and $\hat{a}_k^\dagger$. For homogeneous condensates, we obtain a k-independent decay rate $\gamma$ from Eq. (5).

The atomic operators $\hat{a}_k$ and $\hat{a}_k^\dagger$ are related to the phononic quasi-particle operators $\hat{b}_k$ and $\hat{b}_k^\dagger$ via the Bogoliubov transformation (6) which corresponds to a unitary squeezing operation $\hat{U}_k$ for each mode $k$.
\[
\hat{a}_k = \alpha_k \hat{b}_k + \beta_k \hat{b}_k^\dagger = \hat{U}_k \hat{b}_k \hat{U}_k^\dagger.
\]
(23)
If we directly insert the above Bogoliubov transformation $\hat{a}_k = \alpha_k \hat{b}_k + \beta_k \hat{b}_k^\dagger$ into Eq. (22) and neglect all counter-rotating terms such as $\hat{b}_k^\dagger$, where the time-evolution is generated by Eq. (15), we recover Eq. (16) for homogeneous condensates. In this form, the k-dependence of the Bogoliubov coefficients $\alpha_k$ and $\beta_k$ entails a k-dependence of the rates $\gamma_k$ and $\gamma_k^c$ discussed after Eq. (21).

However, another representation can be more convenient: Since the original atomic operators $\hat{a}_k$ are basically the Lindblad jump operators in Eq. (22), we can use them as a basis and express everything – including the Hamiltonian $\hat{H}_0$ – in terms of $\hat{a}_k$ and $\hat{a}_k^\dagger$ instead of the phononic operators $\hat{b}_k$ and $\hat{b}_k^\dagger$. Assuming that $\hat{H}_0$ is a bi-linear function of the $\hat{a}_k^\dagger$ and $\hat{a}_k$ (or, equivalently, of the $\hat{b}_k^\dagger$ and $\hat{b}_k$) which does not couple the different modes $k$ with each other, its most general form reads
\[
\hat{H}_0 = \sum_k \left(\omega_k \hat{a}_k^\dagger \hat{a}_k - \frac{i}{2} \hat{a}_k \hat{a}_k^\dagger \hat{a}_k + \frac{i}{2} \hat{a}_k^\dagger \hat{a}_k^\dagger \hat{a}_k \right).
\]
(24)

Using the mode functions $\exp(ik \cdot r)$ for periodic boundary conditions, Eq. (23) would read $\delta_k = \alpha_k \hat{b}_k + \beta_k \hat{b}_k^\dagger$. For reflecting boundary conditions (e.g., Dirichlet or Neumann), one would use sine or cosine functions instead where $k$ and $-k$ correspond to the same mode and thus we may write $\hat{a}_k = \alpha_k \hat{b}_k + \beta_k \hat{b}_k^\dagger$ as in Eq. (23).
Note that, even if the Hamiltonian $\hat{H}_0$ was diagonal in terms of the phononic operators $\hat{b}_k^\dagger$ and $\hat{b}_k$, i.e., had the form of $\hat{H}_0^R$ in Eq. (15), it would still contain non-zero $\Xi_k$-terms in the representation (24). One way to obtain them would be to insert the inverse Bogoliubov transformation (23), i.e., $\hat{b}_k = U_0 \hat{a}_k U_0^\dagger$, into the form $\hat{b}_k^\dagger \hat{b}_k$. However, as the Bogoliubov transformation (23) is precisely chosen in order to diagonalize the original Bogoliubov-de Gennes Hamiltonian $\hat{H}_0$, we can find those $\Xi_k$-terms directly in $\hat{H}_0$ when it is expressed in terms of the atomic operators: Inserting the mean-field split (2) into the atomic Hamiltonian $\hat{H}_0$ containing the interaction term $(\hat{\Psi}_1^\dagger \hat{\Psi}_1^\dagger \hat{\Psi}_1 \hat{\Psi}_1)$, we also get $\chi^2$ and $(\chi \gamma)^2$ terms in the effective Bogoliubov-de Gennes Hamiltonian which translate into $\langle \hat{a}_k^\dagger \hat{a}_k \rangle$ and $\langle \hat{a}_k^2 \rangle^2$ contributions after a Fourier transform. In this case, we would get constant $\Xi_k = \Xi$ for a homogeneous condensate.

In order to study the dynamics following from Eqs. (22) and (24), we consider the expectation values of the number operator $\langle \hat{a}_k^\dagger \hat{a}_k \rangle$ and the anomalous average $\langle \hat{a}_k^2 \rangle$ as well as its complex conjugate. Their evolution equations read

$$\frac{d}{dt} \langle \hat{a}_k^\dagger \hat{a}_k \rangle = -\Xi_k (\langle \hat{a}_k^2 \rangle) - \Xi_k^* (\langle \hat{a}_k^\dagger \hat{a}_k \rangle) - \gamma (\langle \hat{a}_k^\dagger \hat{a}_k \rangle),$$

and for the anomalous average

$$\frac{d}{dt} \langle \hat{a}_k^2 \rangle = -2 i \omega_k (\langle \hat{a}_k \hat{a}_k^\dagger \rangle) - 2 \Xi_k (\langle \hat{a}_k^\dagger \hat{a}_k \rangle) + 1 - \gamma (\langle \hat{a}_k^\dagger \hat{a}_k \rangle).$$

Introducing the vector $\mathbf{w} = (\langle \hat{a}_k \rangle, \langle \hat{a}_k^\dagger \hat{a}_k \rangle, \langle \hat{a}_k^2 \rangle)^\dagger$, this linear system can be cast into the form $\mathbf{w} + \mathbf{M} \cdot \mathbf{w} = \mathbf{s}$ with the source $\mathbf{s} = -2(\Xi_k, 0, \Xi_k)$ and the $3 \times 3$-matrix

$$\mathbf{M} = \begin{pmatrix} \gamma & 2 i \omega_k & 2 \Xi_k \\ 2 \Xi_k & \gamma & 0 \\ 0 & 2 \Xi_k & \gamma - 2 i \omega_k \end{pmatrix},$$

with the eigenvalues $\gamma$ and $\gamma \pm 2 \sqrt{\Xi_k^2 - \omega_k^2}$. Thus, this set of equations can be solved explicitly -- incorporating the results of the previous sections as limiting cases. For example, for $\Xi_k = \omega_k = \beta_k = 0$, we recover Eq. (10).

Note that the above matrix equation just yields the exponential decay $\propto \exp(-\gamma t)$ of the expectation values $\langle \hat{a}_k^\dagger \hat{a}_k \rangle$, $\langle \hat{a}_k^2 \rangle$, and $\langle \hat{a}_k^\dagger \hat{a}_k^\dagger \rangle$. The noise term in Eq. (10) stems from the commutator of the operators $\hat{a}_k$ and $\hat{a}_k^\dagger$ when re-expressing the variance $(X_0^2)$ as a function of those expectation values $\langle \hat{a}_k^\dagger \hat{a}_k \rangle$, $\langle \hat{a}_k^2 \rangle$, and $\langle \hat{a}_k^\dagger \hat{a}_k^\dagger \rangle$. This commutator represents the quantum fluctuations: While the expectation values $\langle \hat{a}_k^\dagger \hat{a}_k \rangle$, $\langle \hat{a}_k^2 \rangle$, and $\langle \hat{a}_k^\dagger \hat{a}_k^\dagger \rangle$ tend to zero under the influence of the decay channel, this is not true for the variance $(X_0^2)$, which tends to unity -- respecting the Heisenberg uncertainty principle.

In analogy, one may derive a closed set of equations for the linear expectation values $\langle \hat{a}_k^\dagger \hat{a}_k \rangle$ and $\langle \hat{a}_k \rangle$. Apart from the $\hat{H}_0$-evolution, we obtain additional decay terms $-\gamma (\langle \hat{a}_k^\dagger \hat{a}_k \rangle)/2$ and $-\gamma (\langle \hat{a}_k \rangle)/2$. Note that we did not assume Gaussian states so far -- this will be the subject of the next section.

## IV. GAUSSIAN STATES

In the following, we restrict our considerations to Gaussian states $\hat{\theta}_k$. To this end, we assume that the undisturbed quasi-particle Hamiltonian $\hat{H}_0$ in Eq. (5) is -- at least to a sufficiently good approximation -- given by a linear combination of terms linear or bi-linear in the operators $\hat{b}_1$ and $\hat{b}_1^\dagger$. Combining these creation and annihilation operators in an operator-valued pseudo-vector $\zeta_J$, the general structure of $\hat{H}_0^\text{Gauss}$ is thus

$$\hat{H}_0^\text{Gauss} = \sum_J \hat{\zeta}_J \Omega_J \hat{\zeta}_J^\dagger + \sum_I \hat{\zeta}_I \delta_I,$$  \hspace{1cm} (28)

where the block matrix $\Omega_J$ contains the single-mode $\Xi_J$ and multi-mode $\Xi_{J,I}$ squeezing rates as well as the single-mode frequencies $\omega_J$ and possible multi-mode rotations $\omega_{J,I}$, while the $\delta_I$ terms generate coherent displacements.

Note that the transformations $U$ to the squeezed reference frame mentioned in the previous Section preserve this structure and just change the parameters $\Omega_{J,I} \rightarrow \Omega_{J,I}$ and $\delta_J \rightarrow \delta_J$.

Under that condition (28), the Lindblad master equation (5) preserves Gaussianity, i.e., it maps initial Gaussian states $\hat{\theta}_k(t = 0)$ to final Gaussian states $\hat{\theta}_k(t)$, see also [51]. Gaussian states strongly simplify the analysis. They are uniquely defined by their displacement vector

$$D_J = \langle \hat{\zeta}_J \rangle$$  \hspace{1cm} (29)

and the covariance matrix

$$\Sigma_{IJ} = \langle \hat{\zeta}_I \hat{\zeta}_J^\dagger \rangle + \langle \hat{\zeta}_J \hat{\zeta}_I^\dagger \rangle - 2 D_I D_J^\dagger,$$\hspace{1cm} (30)

which are the generalization of the expectation values $\langle \hat{b}_I^\dagger \hat{b}_I \rangle$ and $\langle \hat{b}_I \rangle$ as well as $\langle \hat{b}_I^\dagger \hat{b}_I \rangle^*$ (or, equivalently, $\langle \hat{a}_k^\dagger \hat{a}_k \rangle$ and $\langle \hat{a}_k \rangle$ as well as $\langle \hat{a}_k^\dagger \hat{a}_k \rangle^*$) discussed in the previous Section. All higher-order expectation values can be reduced to these two quantities (i.e., the first and second cumulants) via a Wick type expansion.

### A. Parameter estimation

The simple structure of Gaussian states discussed above facilitates several calculations which can be extremely hard for general states. For instance, because general mixed quantum states can be decomposed into pure states in many different ways, it is often necessary to minimize over all possible decompositions (which is referred to as convex roof construction). One example are entanglement measures, another example is the Quantum Fisher Information, see, e.g., [52-54]. This quantity measures how much a state changes if we modify an external parameter $\vartheta$ which occurs in the Hamiltonian $\hat{H}_0$,
for example. Of course, this is relevant for estimating this external parameter \( \vartheta \) by measuring the state.

In terms of the \( \vartheta \)-dependent displacement vector \( D_\vartheta \) and covariance matrix \( \Sigma_\vartheta \) at a given time \( t \), the Quantum Fisher Information (for a Gaussian state) reads \[ F_\vartheta = \frac{1}{2} \frac{\text{Tr}(\{\Sigma_\vartheta^{-1}, \Sigma'_\vartheta\})}{1 + P_{\vartheta}^2} + 2 \left( P_{\vartheta}' \right)^2 \frac{1}{1 - P_{\vartheta}^2} + 2 (D_{\vartheta}')^\dagger \cdot \Sigma_\vartheta^{-1} \cdot D_{\vartheta}' . \] (31)

Here \( P_\vartheta = 1/\sqrt{\det \Sigma_\vartheta} \) denotes the purity of the state and primes denote derivatives with respect to \( \vartheta \). These derivatives describe how much the state changes when modifying the external parameter \( \vartheta \) and with respect to \( \Omega \). They quantify the potential to estimate this change by measuring the state. The achievable accuracy is then given by the Quantum Cramér-Rao bound \[ (\Delta \vartheta)^2 \geq \frac{1}{F_\vartheta}, \] (32)

where we assumed a single measurement. Thus, for high accuracy, a large Quantum Fisher Information \( F_\vartheta \) is necessary. One way to achieve this would be to increase the derivatives \( \Sigma'_\vartheta, P'_\vartheta, \) and \( D'_\vartheta \). However, this is limited by the experimentally available coupling strengths etc. The idea of quantum enhanced sensing is to modify the covariance matrix \( \Sigma_\vartheta \) such that one or some of its eigenvalues are small and thus changes \( \Sigma_\vartheta \) or \( D_\vartheta \) in that direction (i.e., the corresponding eigenvectors) are enhanced by the multiplication with \( \Sigma_\vartheta^{-1} \).

### B. Decoherence

As one would already expect from the results of Sec. III, the impact of decoherence tends to limit the potential of quantum enhanced sensing. In the framework discussed above, this manifests itself in the growth of the small eigenvalues of the covariance matrix \( \Sigma_\vartheta \). If we consider the pure decay channel in Sec. IIA or the evolution within the squeezed reference frame in Sec. IIE, we find the equation of motion for the covariance matrix

\[
\frac{d}{dt} \Sigma_\vartheta = \Omega \cdot \Sigma_\vartheta + \Sigma_\vartheta \cdot \Omega^\dagger - \frac{1}{2} (\Gamma \cdot \Sigma_\vartheta + \Sigma_\vartheta \cdot \Gamma) + \Gamma .
\] (33)

Here \( \Omega \) represents the Hamiltonian evolution and is built from the rates \( \Omega_{IJ} \) in Eq. (28), while \( \Gamma \) is a diagonal matrix containing all the decay rates \( \gamma_I \). Thus, if \( u_i \) is an eigenvector of \( \Sigma_\vartheta \) with a small eigenvalue \( \lambda \), we find that the rate of change of the projection of \( \Sigma_\vartheta \) onto that eigenvector \( u_i \cdot \Sigma_\vartheta \cdot u_i \) scales with the small eigenvalue \( \lambda \) plus the noise term \( \Gamma \cdot u_i \cdot u_i \). Since \( \Gamma \) is a positive matrix (assuming that all \( \gamma_I \) are positive), we see that this poses a quite general limitation of the achievable accuracy.

For the rotating-wave approximation discussed in Sec. IIE, we find a very similar evolution equation

\[
\frac{d}{dt} \Sigma_\vartheta = -\frac{1}{2} (\Gamma_- \cdot \Sigma_\vartheta + \Sigma_\vartheta \cdot \Gamma_-) + \Gamma_+, \quad (34)
\]

where \( \Gamma_\pm \) are again diagonal matrices containing the decay rates \( \gamma^\pm \) in complete analogy to Eq. (19). Note that we did not include the Hamiltonian evolution \( \Omega \) since the above equation refers to the rotating reference frame. As another difference to the evolution equation (33), the decoherence does not drive the system towards the ground state (where \( \Sigma_\vartheta \) would be given by the identity matrix), but to the asymptotic state \( \Sigma_\vartheta = \Gamma_+ \cdot \Gamma_-^{-1} \) corresponding to detailed balance, see equation (A20) in the Appendix for the solution of (34). Apart from that, the main conclusions remain unchanged.

### V. SINGLE-MODE CASE

For a single mode, the most general pure Gaussian state is a squeezed, displaced and rotated state, which can be obtained from the ground state \( |0\rangle \) via the unitary operations \( \hat{S}, \hat{D}, \) and \( \hat{R} \) generated by the respective contributions to the Hamiltonian \( \hat{H}_S = -\xi (\hat{b}^\dagger)^2/2 + \text{h.c.}, \hat{H}_D = i\hat{b} \hat{b}^\dagger + \text{h.c.}, \) and \( \hat{H}_R = \omega b b^\dagger \). Their symplectic representations are \( 2 \times 2 \)-matrices acting on the covariance matrix \( \Sigma \) and displacement vector \( D \), such as \( \Sigma \rightarrow S(r) \cdot \Sigma \cdot S(r)^\dagger \) with the squeezing matrix

\[
S(r) = \begin{pmatrix} \cosh(r) & -\sinh(r) \\ -\sinh(r) & \cosh(r) \end{pmatrix},
\] (35)

for the case of real \( \xi = r \in \mathbb{R} \). Taking the ground state \( |0\rangle \) with \( \Sigma = 1 \) as the initial state, one finds

\[
\Sigma(r) = \begin{pmatrix} \cosh(2r) & -\sinh(2r) \\ -\sinh(2r) & \cosh(2r) \end{pmatrix},
\] (36)

with the two eigenvalues \( \lambda_{\pm} = e^{\pm 2r} \). Thus, for large squeezing, say \( e^{2r} \gg 1 \), one can enhance the sensitivity.

However, as explained above, this pure squeezed state is very vulnerable to decoherence, which adds noise and thereby turns it into a mixed state. For example, the evolution equation (34) with the above state (36) as the initial state \( \Sigma_0 \) can be solved as

\[
\Sigma(t) = e^{-\gamma t} \Sigma_0 + \frac{\lambda^+}{\lambda^-} (1 - e^{-\gamma t}) I .
\] (37)
For short times $t \ll 1/\gamma^-$, we see that the small eigenvalue $\lambda_-$ grows as

$$\lambda_-(t) = e^{-2r} + \gamma^+ t - e^{-2r} \gamma^- t + \mathcal{O}(t^2). \quad (38)$$

Since $e^{-2r} \ll 1$ and $\gamma^+ \geq \gamma^-$, the growth term $\gamma^+ t$ dominates and the quantum enhanced sensitivity deteriorates after a short time $t = \mathcal{O}(e^{-2r}/\gamma^+)$. This goes along with a decay of the purity $P(t) \approx (1 + e^{2r} \gamma^+ t)^{-1/2}$ on the same timescale.

### A. Displacement Scheme

In order to be more explicit, we have to specify how the signal to be measured is coupled to the single mode under consideration. Encoding the parameter $\vartheta$ to be estimated in a pure displacement $D_\vartheta$ into the direction $u_\lambda_-$, where the variance is small, the Quantum Fisher Information $F_\vartheta$ simplifies to $F_\vartheta = 2|\text{tr}[(D_\vartheta)^2]^{-1}$ (see Appendix B 1 for details). Thus, for the initial pure state, the accuracy $\Delta \vartheta$ would be enhanced by the squeezing factor $e^{-r}$. Adding noise, however, the uncertainty rapidly grows as

$$\Delta \vartheta \geq \frac{1}{\sqrt{F_\vartheta}} = \frac{e^{-r}}{\sqrt{2|\text{tr}[D_\vartheta]^2|}} \rightarrow \frac{e^{-r}}{\sqrt{2|\text{tr}[D_\vartheta]^2|}} \sqrt{1 + e^{2r} \gamma^+ t}. \quad (39)$$

Let us illustrate the main mechanism by means of a simple example depicted in Fig. 1. The displacement Hamiltonian $H_D$ does not affect the covariance matrix $\Sigma$ at all, but just creates a displacement vector $D$. The impact of decoherence, on the other hand, strongly affects the covariance matrix $\Sigma$, mainly by increasing the small eigenvalue(s), while its influence on the displacement vector $D$ is very weak. Thus, we may consider the two phenomena quite independently and arrive at the sequence shown in Fig. 1. Here, the small $\lambda_-$ and large $\lambda_+$ eigenvalues of the covariance matrix $\Sigma$ are represented by the minor and major semi-axes of the ellipses in the Wigner representation. Thus, their area is a measure of the purity (corresponding to the determinant of $\Sigma$).

### B. Rotation Scheme

By inspecting Eq. (31), we see that the impact of the small eigenvalue $\lambda_-$ employed for quantum enhanced sensing is even larger for the first term in Eq. (31), which scales quadratically in $\lambda^{-1}$. To exploit this scaling, one could encode the parameter $\vartheta$ in the covariance matrix, which can be achieved by a rotation $R$, for example. The corresponding mechanism is depicted in Fig. 2. For $e^{2r} \gg 1$, we obtain (see Appendix B 2)

$$\Delta \vartheta \geq \frac{1}{\sqrt{F_\vartheta}} \approx e^{-2r} \sqrt{2 + e^{2r} \gamma^+ t}. \quad (40)$$

### C. Squeezing Scheme

Finally, one can encode the signal $\vartheta$ also in a squeezing operation itself. If we again start from a state squeezed in $X$ direction, as in Figs. 1 and 2, these figures already suggest that encoding the signal $\vartheta$ into a squeezing in exactly the same $X$ direction (or in the orthogonal $P$ direction) is not the best idea for achieving quantum enhanced sensing. Instead, one should apply a squeezing in a slanting direction (e.g., at $\pm 45^\circ$). Then, for large initial squeezing $e^r \gg 1$ and small signal squeezing (i.e., small $\vartheta$), we get qualitatively the same picture as in Fig. 2 (a detailed calculation can be found in Appendix B 3).
VI. EXPERIMENTAL PARAMETERS

Let us provide a rough estimate of the characteristic parameters. Assuming a uniform rubidium BEC with a density of \( \rho_c = 10^{14} \text{ cm}^{-3} \) and the decay constant \( D \approx 5.8 \times 10^{-30} \text{ cm}^6 \text{s}^{-1} \) [46] yields \( \gamma = 3D\rho_c^2 \approx 0.2 \text{s}^{-1} \). Similarly, a ytterbium BEC with \( D \approx 4 \times 10^{-30} \text{ cm}^6 \text{s}^{-1} \) [47] and the same density gives \( \gamma \approx 0.1 \text{s}^{-1} \). Making the condensates more dilute \( \rho_c = 10^{13} \text{ cm}^{-3} \) reduces \( \gamma \) by two orders of magnitude and leads to longer inverse damping times between 500 s and 1000 s. These time scales limit the life-time of the condensate itself and of the phononic excitations, but do also pose restrictions on quantum enhanced sensing. Note that the noise rate \( \gamma^+ \) is even larger than the above values of \( \gamma \).

A. Comparison to Landau & Beliaev damping

Let us compare the above values to other decoherence and damping channels often discussed in BECs, i.e., Landau and Beliaev damping. Landau damping corresponds to a process where two quasi-particle excitations (i.e., atoms in excited motional states) interact such that their energy and momentum are combined into a single higher energetic quasi-particle leaving the remaining atom as a condensate atom. It was initially discussed in [59–58]. An expression for the damping constant \( \gamma \) in a uniform BEC for general temperatures was derived in [59] [60]. As one would expect, Landau damping is suppressed for low temperatures \( T \) (where only a few excitations are present) and scales with \( T^3 \). Furthermore, it grows linearly with the quasi-particle momentum. Assuming a low temperature of 200 pK and a dilute and inversely proportional to the number of phonons, which is usually referred to as the Heisenberg limit – in contrast to the usual Poisson limit \( \Delta \theta \sim 1/\sqrt{\langle n \rangle} \), which is also referred to as shot-noise limit or standard quantum limit. However, the deterioration of the Heisenberg limit is not caused by the decay of the excitation quanta – which occurs on a rather long time scale \( t = \mathcal{O}(1/\gamma^-) \). Instead, it is caused by adding noise, which happens on a time scale \( t = \mathcal{O}(e^{-2\gamma^+}) \), i.e., much faster (for large squeezing).

Note that the Heisenberg scaling \( \Delta \theta \sim 1/\langle \hat{n} \rangle \) can also be realized via the displacement scheme [39] if we do not just use a strong squeezing to reduce \( \chi_\perp = e^{-2r} \), but also employ a large displacement. Of course, a large displacement does also imply a large number of phonons \( \langle \hat{D}^+ \rangle \sim \langle \hat{n} \rangle \) such that the available signal \( \langle \hat{D}^+ \rangle \) scales with \( \langle \hat{n} \rangle \), giving the total scaling \( \Delta \theta \sim 1/\langle \hat{n} \rangle \).

In both cases, the minimum uncertainty \( \Delta \theta \) is determined by the Heisenberg limit \( \Delta \theta \sim 1/\langle \hat{n} \rangle \), as expected. Note that the number of phonons \( \langle \hat{n} \rangle \) must be much smaller than the total number \( N_c \) of atoms in the condensate for the linearized quasi-particle description to apply.

D. Sensing continuously encoded parameters

Above, we considered the simplified situation where the parameter \( \theta \) is encoded in the initial state of the phonon field before its open dynamics leads to deterioration of quantum sensitivity. This corresponds to the case of fast encoding of \( \theta \) in comparison to the time scales given by \( 1/\gamma^- \) and \( 1/\gamma^+ \). If the time scale of the free dynamics and the duration of the encoding process are similar, we have to consider the case of continuous encoding of \( \theta \), in principle. However, for small values of \( \theta \) and \( \gamma^+ t \), the dynamics of the phonon field differs from the case of instantaneous encoding by terms proportional to products and higher powers of \( \theta \) and \( \gamma^+ t \). Neglecting these higher order contributions, we recover the above results.

If the rate of change of the encoded parameter \( \theta \) is to be estimated, there exists an optimal measurement duration depending on \( \gamma^+ \).

E. Heisenberg Limit

Note that, for large squeezing \( e^{2r} \gg 1 \), the small eigenvalue \( \lambda_- = e^{-2r} \) of the pure state scales with the inverse of the number \( \langle \hat{n} \rangle \) of excitation quanta (phonons), which is given by \( \langle \hat{n} \rangle = \sinh^2(r) \). Thus, the accuracy \( \Delta \theta \) scales

---

4 For the case of continuously encoded squeezing, detailed calculations can be found in Appendix B.
fairly large (elongated) BEC with size 200 $\mu$m and density $\rho_c = 10^{13}$ cm$^{-3}$, the associated damping rate $\gamma$ can be suppressed down to $10^{-5}$ s$^{-1}$. In this regime, it is negligible in comparison with the three-body-loss – unless very high quasi-particle momenta are considered.

Beliaev damping corresponds to the scattering of a quasi-particle excitation and a condensate atom leading to two quasi-particle excitations that share the kinetic energy and the momentum of the initial excitation. Because it does not require a second quasi-particle excitation, it can also exist at zero temperature – but it scales with the fifth power of the quasi-particle momentum [60]. Thus, for low momenta, Beliaev damping can be suppressed down to rates $10^{-9}$ s$^{-1}$ (i.e., even more strongly than Landau damping), but it can become dominant for larger momenta.

For higher temperatures and/or larger quasi-particle momenta, Landau and Beliaev damping start to dominate in comparison to three-body loss. However, their consequences are completely analogous to the results discussed above: On the linearized quasi-particle level, their impact is described by the same effective master equation [16], just with adapted decay rates $\gamma_{\pm}$, see also [40] and Appendix D.

It should be stressed here that the above considerations are based on the linearized quasi-particle picture. If too many quasi-particles are present, higher-order nonlinearities may become important and induce additional effects such as de-phasing.

B. Example Application: Gravity Sensing

To give an intuition for the effect of decoherence in an experimental situation, we will present the sensing of oscillating gravitational fields as an example application in the following. Note that it is not our intention to give a full experimental proposal, which requires several steps: First, one has to make sure that the oscillating gravitational field changes the quantum state of the probe (i.e., the condensate) enough to be detectable in principle. Second, one has to find a way to actually detect this change experimentally. Third, one has to distinguish the measured signal from noise and background processes. Here, we mainly focus on the first step – if it cannot be accomplished successfully, there is no need to consider the further steps.

In [31], it has been theoretically investigated how the time-dependent gravitational field of a small oscillating gold sphere acts on a nearby BEC. In particular, it has been shown that phonon modes respond to the gravitational field, especially if the oscillation of the gravitational acceleration is on resonance with a phonon mode. In that case (direct driving), the interaction between the phonon mode and the gravitational field can be represented by a displacement Hamiltonian $\hat{H}_D$. Starting in the ground state (i.e., no initial squeezing), the displacement is detectable (in principle) if it corresponds to an expectation value of the phonon number operator (in this mode) of order unity[5].

As an explicit example, let us consider a cylindrical ytterbium BEC of length $L$ and diameter $d$, which is axially oriented with respect to the source mass’ motion. To simplify the comparison, we consider the same parameters as discussed in [31]. Thus, we assume a rather large BEC, where $L$ and $d$ both are approximately 300 $\mu$m, containing $2 \times 10^9$ condensed atoms. This corresponds to a rather low density of $10^{13}$ cm$^{-3}$, for which the damping rates have already been discussed above. If we consider a gold sphere of 200 g, oscillating with a frequency of 8 Hz and an amplitude of $2 \times 10^{-3}$ m at an average distance of 3 mm from the source mass’ surface to the BEC, the impact of the gravitational field on the phonon mode with the wave vector $\mathbf{k} = (10\pi/L, 0, 0)$ pointing in the axial direction, would lead to a detectable displacement after 10 s.

For the displacement scheme, the fundamental uncertainty for a measurement is given by equation (39). More explicitly, the change of the displacement is proportional to the source mass. Thus, in the absence of decoherence, an initial squeezed state implies a scaling of the minimum detectable mass $\Delta m$ as $e^{-r}$. For example, for $r = 1, r = 2$ and $r = 5$ and the system parameters above, this corresponds to a detectable mass of about 70 g, 30 g and 1 g, respectively.

In the ideal case, a squeezing of $r = 5$ corresponds to an increase in sensitivity of more than two orders of magnitude. Note that this corresponds to a mean phonon number of $\langle \hat{n} \rangle = \sinh^2(r) \approx 5.5 \times 10^3$, i.e., a highly excited state (with a correspondingly large energy). Apart from the experimental challenges to actually create (and detect) such a state, one should carefully scrutinize the underlying approximations for such a highly excited state, e.g., regarding the impact of non-linearities (which might induce de-phasing etc.).

Moreover, even with the small value of $\gamma \sim 10^{-3}$ s$^{-1}$, leading to $\gamma_k \sim 10^{-2}$ s$^{-1}$ for the specific mode under consideration, the quantum enhancement of the sensitivity would already be decreased to a factor 4 after 10 s. This corresponds to a detectable mass of 50 g (instead of 1 g in the ideal case).

As the change of displacement is proportional to the driving time $t$ (see [31]) while the decrease in sensitivity due to decoherence is proportional to the square root of $t$ (for large squeezing), the sensitivity still increases with driving time – provided that the resonance condition can be maintained during that time and that the BEC is not disturbed too much.

[5] Still, measuring a single phonon in a BEC is a non-trivial task, see, e.g., the Conclusions section of [31] or [Detection Scheme for Acoustic Quantum Radiation in Bose-Einstein Condensates, Ralf Schützhold, Phys. Rev. Lett. 97, 190405 (2006)].
VII. CONCLUSIONS AND DISCUSSIONS

For the phonon modes of Bose-Einstein condensates in ultra-cold atomic vapor, we studied the impact of decoherence caused by the omnipresent process of three-body loss on quantum enhanced sensing. In contrast to other effects such as Landau and Beliaev damping, this process cannot be suppressed by going to ultra-low temperatures or energies. Three-body loss can be suppressed by making the condensate more dilute or by reducing the atomic interaction strength \[44,61\], but this would also diminish other important quantities such as the speed of sound or the total number of atoms in the BEC. As a result, the overall dynamics of the BEC would become slower or the available phase space (e.g., possible amount of squeezing and maximum number of phonons) would shrink – which poses additional challenges for sensing schemes.

Another way of suppressing three-body loss would be to confine the BEC spatially, i.e., to make it effectively lower dimensional (see Appendix C for a detailed discussion). In that case, a reduction of dimension to 1d can lead to a suppression of the loss rate by several orders of magnitude for ultra-low temperatures in the weakly interacting Bogoliubov regime \[62,64\] when the atomic density is kept constant, implying the corresponding reduction of the number of atoms. In the strongly interacting Tonks-Girardeau regime, the suppression is much more significant and three-body loss can be reduced very strongly. However, the restriction to the Tonks-Girardeau regime leads to an upper bound on the atomic density for a fixed 1d scattering length \[65\]. This implies an upper bound on the number of atoms that can be confined in the same trap.

It has been shown that controlling the environment may lead to a partial retrieval of quantum enhancement in sensing \[65,66\]. Therefore, the effect of three-body loss might be limited by precisely monitoring dimer molecules and excess atoms (see also \[67\]) even though this is experimentally very challenging.

Depending on the squeezing parameter \(r\) employed for quantum enhanced sensing, we found a rapid deterioration of precision on a time scale \(t = \mathcal{O}(1/\gamma^{-})\). This hierarchy of time scales is analogous to the difference between relaxation time \(T_1\) and coherence time \(T_2\) known from quantum information theory, for example.

In principle, one could counteract the decoherence induced growth of uncertainty by permanent squeezing. However, the required squeezing rate \(\Xi\) would be quite large \(\Xi = \mathcal{O}(2r/\gamma^{-})\) and thus experimentally challenging. In addition, since this squeezing operation should demagnify the direction \(u_\lambda\) corresponding to the small eigenvalue \(\lambda_\lambda = e^{-2r}\) of the covariance matrix, i.e., precisely the same direction as the signal to be measured, there is the danger to reduce the signal as well, which would be counterproductive. This can be understood by inspecting Fig. 1 for example. In order to enhance the sensitivity for measuring a displacement in \(X\) direction, one would squeeze the initial state in that direction as well. However, in order to counteract the decoherence induced growth of uncertainty, one would also have to squeeze the final state in the same direction, which would also demagnify the signal to be measured. In addition, such a squeezing would also generate further excitations, i.e., a larger number of phonons, which pose further problems.

We would also like to stress that we considered general bounds on the achievable accuracy based on the behavior of the variances or the Quantum Fisher Information \[51\], but we did not provide a concrete measurement scheme (which can also be quite challenging experimentally). Nevertheless, our general limits on the measurement time \(t\) and the squeezing \(r\) should be taken into account for proposals involving quantum enhanced sensing applications based on BECs.

Appendix A: Time evolution of displacement vector and 
covariance matrix

In equation (16), we found that, in the rotating-wave approximation, 
the time evolution of the density matrix of 
the field \( \hat{b} \) and for 

\[
\text{In equation (16), we found that, in the rotating-wave approximation, the time evolution of the density matrix of the field } \hat{b} \text{ and for } \Gamma_i = \Gamma_i^+ \pm \Gamma_i^-, \text{ the time evolution of expectation values of first order and second order operators becomes}
\]

\[
\frac{d(\hat{b}_i)}{dt} = -i \text{Tr} \left( \hat{b}_i \left[ \hat{H}_0, \hat{b} \right] \right) + \gamma_i^+ \text{Tr} \left( \hat{b}_i \left( \hat{b}_i \hat{b}_i \hat{b}_i - \frac{1}{2} \left\{ \hat{b}_i \hat{b}_i, \hat{b}_i \right\} \right) \right) + \gamma_i^- \text{Tr} \left( \hat{b}_i \left( \hat{b}_i \hat{b}_i \hat{b}_i - \frac{1}{2} \left\{ \hat{b}_i \hat{b}_i, \hat{b}_i \right\} \right) \right)
\]

\[
\text{and for } n \neq m
\]

\[
\frac{d(\hat{b}_i \hat{b}_j)}{dt} = \frac{d(\hat{b}_i \hat{b}_j)}{dt} = -i(\omega_j - \omega_i) + (\gamma_i^+ + \Gamma_j^-) / 2) \hat{b}_i \hat{b}_j
\]

\[
\frac{d(\hat{b}_i \hat{b}_j \hat{b}_j)}{dt} = \frac{d(\hat{b}_i \hat{b}_j \hat{b}_j)}{dt} = -i(\omega_j + \omega_i) + (\gamma_i^- + \Gamma_j^+) / 2) \hat{b}_i \hat{b}_j.
\]

\[
\frac{d(\hat{b}_i \hat{b}_j \hat{b}_j)}{dt} = \frac{d(\hat{b}_i \hat{b}_j \hat{b}_j)}{dt} = -i(\omega_j - \omega_i) + (\gamma_i^- + \Gamma_j^+) / 2) \hat{b}_i \hat{b}_j
\]

\[
\frac{d(\hat{b}_i \hat{b}_j \hat{b}_j \hat{b}_j)}{dt} = \frac{d(\hat{b}_i \hat{b}_j \hat{b}_j \hat{b}_j)}{dt} = -i(\omega_j + \omega_i) + (\gamma_i^+ + \Gamma_j^-) / 2) \hat{b}_i \hat{b}_j.
\]
Defining the rotating frame

\begin{align}
\langle \hat{b}_1 \rangle &= \langle \hat{b}_1 \rangle e^{i \omega_1 t} \\
\langle \hat{b}_1^2 \rangle &= \langle \hat{b}_1 \rangle e^{2i \omega_1 t} \\
\langle \hat{b}_1 \hat{b}_1 \hat{b}_2 \rangle &= \langle \hat{b}_1 \hat{b}_1 \rangle \\
\langle \hat{b}_1^2 \hat{b}_2 \rangle &= \langle \hat{b}_1 \rangle e^{(\omega_1 - \omega_2) t} \\
\langle \hat{b}_1 \hat{b}_2 \rangle &= \langle \hat{b}_1 \rangle e^{(\omega_1 + \omega_2) t},
\end{align}

the differential equations become

\begin{align}
\frac{d\langle \hat{b}_1 \rangle}{dt} &= -\frac{\gamma_1}{2} \langle \hat{b}_1 \rangle \\
\frac{d\langle \hat{b}_1^2 \rangle}{dt} &= -\gamma_1^+ \langle \hat{b}_1^2 \rangle \\
\frac{d\langle \hat{b}_1 \hat{b}_1 \rangle}{dt} &= -\gamma_1^+ \langle \hat{b}_1 \hat{b}_1 \rangle + \gamma_1^-, \\
\frac{d\langle \hat{b}_1^2 \hat{b}_1 \rangle}{dt} &= -\gamma_1^+ \langle \hat{b}_1^2 \hat{b}_1 \rangle + \gamma_1^- \\
\frac{d\langle \hat{b}_1 \hat{b}_2 \rangle}{dt} &= -\gamma_1^+ \langle \hat{b}_1 \hat{b}_2 \rangle + \gamma_1^-.
\end{align}

and for \( n \neq m \)

\begin{align}
\frac{d\langle \hat{b}_1 \hat{b}_2 \rangle}{dt} &= -\gamma_1^- + \gamma_2^- \langle \hat{b}_1 \hat{b}_2 \rangle \\
\frac{d\langle \hat{b}_1 \rangle}{dt} &= -\gamma_1^- + \gamma_2^- \langle \hat{b}_1 \rangle.
\end{align}

The solutions to these differential equations are easily found as

\begin{align}
\langle \hat{b}_1 \rangle &= e^{-\gamma_1 t/2} \langle \hat{b}_1 \rangle_0 \\
\langle \hat{b}_1^2 \rangle &= e^{-\gamma_1 t} \langle \hat{b}_1^2 \rangle_0 \\
\langle \hat{b}_1 \hat{b}_1 \rangle &= e^{-\gamma_1 t} (\langle \hat{b}_1 \hat{b}_1 \rangle_0 - \gamma_1^+ / \gamma_1^-) + \gamma_1^+ / \gamma_1^-,
\end{align}

and for \( n \neq m \)

\begin{align}
\langle \hat{b}_1 \hat{b}_2 \rangle &= e^{-\gamma_1 t + \gamma_2 t/2} \langle \hat{b}_1 \hat{b}_2 \rangle_0 \\
\langle \hat{b}_1 \rangle &= e^{-\gamma_1 t + \gamma_2 t/2} \langle \hat{b}_1 \rangle_0.
\end{align}

We define the operator valued vector \( \hat{\xi} = (\hat{b}_1, \hat{b}_1^\dagger, ..., \hat{b}_1, \hat{b}_1^\dagger, ...)^T_0 \) containing all creation and annihilation operators of the quasi-particle field \( \hat{\chi} \) and \( \hat{\xi}^\dagger = (\hat{b}_1, \hat{b}_1^\dagger, ..., \hat{b}_1, \hat{b}_1^\dagger)^T_0. \) In this basis, the time evolution of the displacement vector and covariance matrix become in the co-rotating frame

\begin{align}
\mathbf{D}(t) &= \mathbf{R}^*(t) \cdot \langle \hat{\xi} \rangle_t = e^{-\Gamma_{-} t/2} \cdot \mathbf{D}(0) \\
\mathbf{\Sigma}(t) &= \mathbf{R}^*(t) \cdot \left\{ \langle \hat{\xi} - \mathbf{D}(t), (\hat{\xi} - \mathbf{D}(t))^T \rangle_t \right\} \cdot \mathbf{R}(t) \\
&= e^{-\Gamma_{-} t/2} \cdot (\mathbf{\Sigma}(0) - \mathbf{\Sigma}_\infty) \cdot e^{-\Gamma_{-} t/2} + \mathbf{\Sigma}_\infty,
\end{align}

where \( \mathbf{\Sigma}_\infty = \mathbf{\Gamma}_+ \cdot \mathbf{\Gamma}_-^{-1} \) and the diagonal matrices \( \mathbf{\Gamma}_\pm \) and \( \mathbf{R}(t) \) are defined as \( \langle \mathbf{\Gamma}_\pm \rangle_{1f-1} = \langle \mathbf{\Gamma}_\pm \rangle_{2f} = \gamma_1^\pm \) and \( \mathbf{R}(t)_{1f-1} = e^{-i \omega_1 t}, \mathbf{R}(t)_{2f} = e^{i \omega_1 t} \), respectively. Equation (A20) is the solution of equation (34) in the main text.

**Appendix B: Parameter estimation with a squeezed vacuum state**

For a single mode squeezed state

\[ \hat{\xi}(0) = \hat{\xi}_\text{vac}(\xi) \hat{\xi}(\xi)^\dagger, \]

(B1)
where $\hat{S}_I(\zeta) = \exp((\zeta^* \hat{b}_I^2 - \zeta \hat{b}_I^{2})/2)$ is the squeezing operator with $\zeta = re^{i\theta}$, we have

$$\Sigma(t)_I = e^{-\gamma t} \mathbf{S}_I(\zeta) \cdot \mathbf{S}_I(\zeta) + \frac{\gamma}{\gamma I} (1 - e^{-\gamma t}) \mathbb{I}$$  \hspace{1cm} (B2)

where

$$\mathbf{S}_I(\zeta) = \begin{pmatrix} \cosh(r) & -e^{2i\theta} \sinh(r) \\ -e^{-2i\theta} \sinh(r) & \cosh(r) \end{pmatrix}.$$  \hspace{1cm} (B3)

is the single mode squeezing operator’s action on mode $I$. Without loss of generality, we assume $\theta = 0$ in the following.

1. Estimation of displacement

We consider an additional displacement $\hat{D}_I(\mu)$, where $\mu = |\mu|e^{i\varphi_\mu}$. This does not change the covariance matrix and, for a squeezed vacuum state, the displacement vector simply becomes

$$\mathbf{D}(t)_I,\mu = (\mu, \mu^*) \mathbb{P}.$$  \hspace{1cm} (B4)

The quantum Fisher information for the estimation of $|\mu|$ is then given as

$$F_{|\mu|}(t) = 2 \left( \mathbf{D}(t)_I,\mu \right)^* \mathbf{D}(t)_I,\mu \cdot \Sigma(t)_I^{-1} \cdot \mathbf{D}(t)_I,\mu,$$  \hspace{1cm} (B5)

where

$$\mathbf{D}(t)_I,\mu = \frac{d}{d\epsilon} \mathbf{D}(t)_I,|\mu|e^{i\varphi_\mu} \bigg|_{\epsilon=0} = (e^{i\varphi_\mu}, e^{-i\varphi_\mu}) \mathbb{P}. $$  \hspace{1cm} (B6)

Again, without loss of generality, we assume $\theta = 0$. In the eigenbasis of $\Sigma(t)_I$, we find

$$\mathbf{D}(t)_I,\mu = \sqrt{2}(\cos(\varphi_\mu), -i \sin(\varphi_\mu)) \mathbb{P}$$  \hspace{1cm} (B7)

and we find that the QFI is maximized for $\varphi_\mu = 0$ leading to

$$F_{|\mu|}(t) = 4\lambda_-(t)^{-1}. $$  \hspace{1cm} (B8)

We find that quantum enhanced sensing of the amplitude of displacement with a squeezed vacuum state has a sensitivity that scales at most with $1/\sqrt{\langle \hat{n} \rangle}$. Let us assume that we want to estimate the phase of a displacement. In that case,

$$\mathbf{D}(t)_I,\mu = \frac{d}{d\epsilon} \mathbf{D}(t)_I,|\mu|e^{i(\varphi_\mu + \epsilon)} \bigg|_{\epsilon=0} = |\mu|(i e^{i\varphi_\mu}, -i e^{-i\varphi_\mu}) \mathbb{P} $$  \hspace{1cm} (B9)

and

$$\mathbf{D}(t)_I,\mu = -\sqrt{2}|\mu|(\sin(\varphi_\mu), i \cos(\varphi_\mu)) \mathbb{P}. $$  \hspace{1cm} (B10)

We find that the QFI is maximized for $\varphi_\mu = \pi/2$ leading to

$$F_{|\mu|}(t) = 4|\mu|^2 \lambda_-(t)^{-1}. $$  \hspace{1cm} (B11)

Now, the corresponding sensitivity scales with the product of the square root of the number of phonons in the initial state and the square root of the number of phonons $|\mu|^2$ created by the signal. This can be associated with Heisenberg scaling if the number of squeezed phonons $\sinh^2(r)$ is of the same order as $|\mu|^2$ and a small signal is enhanced to achieve the amplitude $|\mu|$.
2. Estimation of a rotation angle

We apply an additional rotation \( \hat{R}_I(\vartheta_s) = \exp(-i\vartheta_s \hat{b}_I^\dagger \hat{b}_I) \) of a Gaussian state acts on the covariance matrix as

\[
\Sigma(t)_I,\vartheta_s = R_I(\vartheta_s) \cdot \Sigma(t)_I \cdot R_I(\vartheta_s)^{\dagger}
\]

where \( R_I(\vartheta_s) = \text{diag}(e^{-i\vartheta_s}, e^{i\vartheta_s}) \). For the QFI, we have

\[
F_{\vartheta_s}(t) = \frac{1}{2(1 + P(t)^2)} \text{Tr} \left[ \left( \Sigma(t)_{I,\vartheta_s}^{-1} \Sigma(t)_{I,\vartheta_s} \right)^2 \right], \tag{B12}
\]

where

\[
\Sigma(t)_{I,\vartheta_s}^{-1} = R_I(\vartheta_s) \cdot \Sigma(t)_I^{-1} \cdot R_I(\vartheta_s)^{\dagger}
\]

\[
\Sigma(t)_I,\vartheta_s = \frac{d}{d\vartheta_s} \Sigma(t)_I,\vartheta_s = \Omega \cdot R_I(\vartheta_s) \cdot \Sigma(t)_I \cdot R_I(\vartheta_s)^{\dagger} \cdot \Omega - R_I(\vartheta_s) \cdot \Sigma(t)_I \cdot R_I(\vartheta_s)^{\dagger} \cdot \Omega
\]

and \( \Omega = \text{diag}(-i,i) \). Also, we find

\[
\text{Tr} \left[ \left( \Sigma(t)_I^{-1} \Sigma(t)_I \right)^2 \right] = \text{Tr} \left[ \left( \Sigma(t)_I^{-1}(\Omega \cdot \Sigma(t)_I - \Sigma(t)_I \cdot \Omega) \right)^2 \right], \tag{B15}
\]

which means that the estimation of phase with a squeezed state does not depend on the base point \( \vartheta_s \). In the eigenbasis of \( \Sigma(t)_I \), we find

\[
\Omega^{eb} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}
\]

and

\[
(\Omega \cdot \Sigma(t)_I - \Sigma(t)_I \cdot \Omega)^{eb} = i(\lambda_-(t) - \lambda_+(t)) \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}
\]

\[
\Sigma(t)_I^{-1} \Omega^{eb} \left( \Omega \cdot \Sigma(t)_I - \Sigma(t)_I \cdot \Omega \right)^{eb} = i(\lambda_-(t) - \lambda_+(t)) \begin{pmatrix} 0 & -1 \\ \lambda_-(t)^{-1} & 0 \end{pmatrix}
\]

Therefore,

\[
\text{Tr} \left[ \left( \Sigma(t)_I^{-1}(\Omega \cdot \Sigma(t)_I - \Sigma(t)_I \cdot \Omega) \right)^2 \right] = 2(\lambda_-(t) - \lambda_+(t))^2 \lambda_-(t)\lambda_+(t) \tag{B19}
\]

We obtain for the QFI

\[
F_{\vartheta_s}(t) = \frac{(\lambda_-(t) - \lambda_+(t))^2}{\lambda_-(t)\lambda_+(t) + 1} \tag{B20}
\]

For \( e^{-2r} \ll 1 \) and \( \gamma_{\vartheta} I t \ll 1 \), we obtain

\[
\Delta \vartheta_s = \frac{1}{\sqrt{F_{\vartheta_s}}} \approx e^{-2r} \sqrt{2 + e^{2r} \gamma_{\vartheta} t}. \tag{B21}
\]

3. Estimation of the squeezing amplitude

Now, let us apply an additional squeezing \( \hat{S}_I(\nu) \), where \( \nu = se^{2i\vartheta_s} \) and bound the sensitivity for estimating the parameter \( s \). The action on the covariance matrix is

\[
\Sigma(t)_{I,\nu} = S_I(\nu) \cdot \Sigma(t)_I \cdot S_I(\nu). \tag{B22}
\]

---

6 We recover the result of [55] equation (16) with \( \alpha = 0 \), \( \lambda_-(t) = 1/(P\sigma^2) \) and \( \lambda_+(t) = \sigma^2/P_0 \).
The quantum Fisher information for the estimation of $s = |\nu|$ is

$$F_s(t) = \frac{1}{2(1 + P_v(t)^2)} \text{Tr} \left[ \left( \Sigma(t)'^{-1} \cdot \Sigma(t)'_{I,\nu} \right)^2 \right],$$  \hfill (B23)

where

$$\Sigma(t)'_{I,\nu} = \frac{d}{d\phi} \Sigma_{I,ccc^\phi}(t) \bigg|_{\phi=0} = \bar{\Sigma}(\phi_v) \cdot \Sigma(t)'_{I,\nu} \cdot \Sigma(t)'_{I,\nu}^{-1} \cdot \bar{\Sigma}(\phi_v)$$

and

$$\bar{\Sigma}(\phi_v) = \frac{d}{d\phi} S_{(se^i\phi_v)} \bigg|_{\phi=0} = \begin{pmatrix} \sinh(s) & -e^{2i\phi_v} \cosh(s) \\ -e^{-2i\phi_v} \cosh(s) & \sinh(s) \end{pmatrix}.$$  \hfill (B25)

We can rewrite the QFI as

$$F_{\nu}(t) = \frac{1}{(1 + P_v(t)^2)^2} \left( \text{Tr} \left[ \left( \bar{\Sigma}(\phi_v) \cdot \Sigma(t)'_{I,\nu} \right)^2 + \text{Tr} \left[ \bar{\Sigma}(\phi_v) \cdot \Sigma(t)'_{I,\nu} \cdot \Sigma(t)'_{I,\nu}^{-1} \cdot \bar{\Sigma}(\phi_v) \cdot \Sigma(t)'_{I,\nu} \right] \right) \right.$$  \hfill (B26)

We transform into the eigenbasis of $\Sigma(t)'_I$ such that

$$\Sigma(t)'_I^\text{eb} = e^{-\gamma_+ t} \begin{pmatrix} e^{-2r} & 0 \\ 0 & e^{2r} \end{pmatrix} + \frac{\gamma_+}{\gamma_+'} (1 - e^{-\gamma_+ t}) 1 = \begin{pmatrix} \lambda_-(t) & 0 \\ 0 & \lambda_+(t) \end{pmatrix},$$

$$\bar{\Sigma}(\phi_v)^\text{eb} \cdot \Sigma(t)'_{I,\nu}^{-1} \cdot \bar{\Sigma}(\phi_v) \cdot \Sigma(t)'_{I,\nu}^{-1} \cdot \Sigma(t)'_{I,\nu} = \begin{pmatrix} \cos(2\phi_v) & -i \sin(2\phi_v) \\ i \sin(2\phi_v) & \cos(2\phi_v) \end{pmatrix},$$  \hfill (B28)

and

$$\Sigma(t)'_{I,\nu} = \begin{pmatrix} \lambda_-(t) + \lambda_+(t) + (\lambda_+-t) \cos(4\phi_v) & \frac{(\lambda_+-t)-\lambda_-(t)}{2\lambda_+(t)} \sin(4\phi_v) \\ -i\frac{(\lambda_+-t)-\lambda_-(t)}{2\lambda_+(t)} \sin(4\phi_v) & \lambda_-(t)+\lambda_+(t) - (\lambda_+-t) \cos(4\phi_v) \end{pmatrix}. $$  \hfill (B29)

Finally, we find

$$F_s(t) = \frac{(\lambda_-(t) + \lambda_+(t))^2}{2(\lambda_-(t)\lambda_+(t) + 1)} \approx \frac{\lambda_+(t)}{\lambda_-(t)\lambda_+(t) + 1},$$  \hfill (B30)

We see that quantum enhancement is maximized for $\phi_v = \pm \pi/4 + m \pi/2$ with integer $m$. In that case, we obtain for the QFI

$$F_s(t) = \frac{(\lambda_-(t) + \lambda_+(t))^2}{2(\lambda_-(t)\lambda_+(t) + 1)} \approx \frac{\lambda_+(t)}{\lambda_-(t)\lambda_+(t) + 1},$$  \hfill (B31)

which is approximately the same as the result for estimation of rotation above.

4. **Continuous squeezing of a squeezed probe state**

We consider the continuous squeezing of an initial probe state by

$$\hat{H}_S = -\Xi \left( e^{2i\phi_v} \hat{b}_0^2 - e^{-2i\phi_v} \hat{b}_0^2 \right) / 2,$$  \hfill (B32)

for which the time evolution of the co-rotating covariance matrix is given as

$$\Sigma(t)'_{I,\Xi} = \Sigma_{\Xi} + e^{-\gamma_+ t} \Sigma_{\Xi}(t) \cdot (\Sigma(0)_{I,\Xi} - \Sigma_{\Xi}) \cdot \Sigma_{\Xi}(t)$$  \hfill (B33)

where $\Sigma(0)_{I} = S_I(\zeta)S_I(\zeta)$ and

$$S_{\Xi}(t) = \begin{pmatrix} \cosh(\Xi t) & -e^{2i\phi_v} \sinh(\Xi t) \\ -e^{-2i\phi_v} \sinh(\Xi t) & \cosh(\Xi t) \end{pmatrix}. $$  \hfill (B34)
recovering the expression for instantaneous squeezing by setting $s = \Xi t$. It is maximized for $\phi_v = \pm \pi/4 + m \pi/2$ with integer $m$ leading to

$$F_\Xi(t) = t^2 \frac{(\lambda_-(t) + \lambda_+(t))^2}{(\lambda_-(t) \lambda_+(t) + 1)} ,$$

(B44)
Appendix C: Three-body loss in lower dimensions

In the main text, we have considered only three-dimensional BECs. However, the rate of three-body loss depends on the dimensionality of the Bose gas. Three-body loss in one-dimensional BECs has been investigated theoretically, for example, in [63, 68] and experimentally, for example, in [62, 63]. In [62], the three-body decay constant $D$ is denoted as $K^{(3D)}_{1D}$ (e.g. compare [62] equation (1) with our equation (14)). There, 1d Bose gases of Rubidium in the Bogoliubov regime are investigated and it is found that $K^{(3D)}_{1D} \approx 1.2(7) \times 10^{-30}$ cm$^6$s$^{-1}$, which they compare to a measurement of $K^{(3)}_{3D}$ to find a 7-fold reduction of the decay constant from 3d to 1d. In [63], the decay constant appears as $D = 3K^{(3)}(3)g^{(3)}$ (see the rate equation in the third paragraph in the left column on page 2), where $K^{(3)}$ incorporates the three-body physics, e.g. the probability of dimer formation in a three-body scattering process, and $g^{(3)}$ is the three-body correlator of the Bose gas, which crucially depends on the geometry of the confinement/trap. Fig. 3 (a) of [63] shows experimental values for $K^{(3)}(3)g^{(3)}$ for Bose gases of Cs between $10^{-30}$ cm$^6$s$^{-1}$ and $10^{-29}$ cm$^6$s$^{-1}$ for a wide range of scattering lengths (tuned by a Feshbach resonance). This gives a decay constant $D$ of about the same order of magnitude as the one we considered for Rb and Yb above. In particular, the results of [63] show at least for Cs, that the decay constants in 3d and 1d are close to each other in the low weakly interacting Bogoliubov regime that we are considering, but the 1d decay constant may be reduced significantly in comparison to the 3d decay constant for larger scattering lengths.

It is reasonable to assume that $K^{(3)}$ does not depend on the dimensions of the Bose gas as long as non of the dimensions of the confinement is smaller than the scattering length or the extension of the dimer created in the process. For Rb-87, a scattering length of $a_{\text{scatt}} \approx 98a_0$ has been reported in [69], where $a_0 \approx 5 \times 10^{-11}$ m is the Bohr radius. The scattering length of Yb-168 can be found in [70] and leads to an interaction constant of approximately $a_{\text{scatt}} \approx 250a_0$. Therefore, for confinement length scales of the order of 100 nm and above, $K^{(3)}$ can be assumed to be the same for Bose gases of Rb and Yb in 3d, 2d and 1d.

Theoretical predictions for $g^{(3)}$ in 1d and its temperature dependence were given in [64]. Fig. 1 of [64] shows $g^{(3)}$ for different temperatures as a function of the dimensionless coupling constant $\gamma$. In the weak coupling Bogoliubov regime $\gamma \lesssim 1$, it is found that the value of the correlator at zero temperature differs from that for large temperatures by about one to two orders of magnitude. When $\gamma \gtrsim \max(1, \sqrt{T/T_D})$ the Tonks-Girardeau regime is reached, where $T_D$ is the temperature, $T_D = h^2n^2/(2mk_B)$, $k_B$ is the Boltzmann constant, $m$ is the atomic mass and $n = N_0/L$ is the 1d density of the Bose gas. In the Tonks-Girardeau regime, $g^{(3)}$ vanishes which leads to vanishing of the decay constant, and thus, vanishing three-body loss. However, $\gamma$ scales with the inverse of the atom density [64], and therefore, the restriction to the Tonks-Girardeau regime leads to a bound on the number of atoms.

For two-dimensional weakly interacting Bose gases, it was predicted in [71, 73] that the breathing mode of the whole gas would be un-damped. A very low damping of that mode was experimentally observed in [74]. A small damping due to vortex–anti-vortex pair creation was predicted later in [75].

Appendix D: Beliaev and Landau damping

When the Hamiltonian $\hat{H}_0$ is expanded based on the split $\chi$, third and fourth order terms in the field operator $\chi$ appear implying interactions that we neglected so far. In particular, the third order terms lead to the damping effects called Landau damping and Beliaev damping that can have significant effects on the state of the field $\chi$. In Landau damping, two quasiparticle excitations (i.e., atoms in excited motional states) interact such that their energy and momentum are combined into a single higher energetic quasi-particle leaving the second quasi-particle as a condensate atom. It was initially discussed in [50, 55]. An expression for the damping constant $\gamma_k$ in a uniform BEC for general temperatures was derived in [58, 60].

In [59], an expression for the damping constant of Landau damping $\gamma_{La}$ in a uniform BEC for quasi-particle energies $\hbar\omega_n \ll k_BT$ was given as

$$\gamma_{La} = \frac{2\sqrt{\pi}h|m^2scatt\rho_0|}{m} F_{La},$$

where

$$F_{La} = 8\sqrt{\pi} \int_0^\infty dx (e^x - e^{-x})^{-2} \left(1 - \frac{1}{2u} - \frac{1}{2u^2}\right)^2,$$

and $u = \sqrt{1 + 4(k_BT/\mu)^2}$. For temperatures $T$ such that $k_BT \ll \mu$, where $\mu = mc_0^2$ is the chemical potential and
\(c_0 = 1/(\sqrt{2m\zeta})\) is the speed of sound of the BEC, and the Landau damping rate becomes [60]

\[
\gamma_{k}^{La} = \frac{3\pi^3 |k|(k_B T)^4}{40 \rho_0 \hbar^2 mc_0^2},
\] (D3)

The Landau damping rate is proportional to the temperature’s fourth power. Therefore, Landau damping can be decreased significantly by lowering the temperature further once the low temperature regime \(k_B T \ll \mu\) is reached.

Beliaev damping is the scattering of a quasi-particle and a condensate atom leading to two quasi-particle excitations that share the kinetic energy and the momentum of the initial quasi-particle. The corresponding damping constant for uniform BECs is given as [60]

\[
\gamma_{k}^{Be} = \gamma_{k}^{Be,0} \left[ 1 + 60 \int_0^1 dx \frac{x^2(x-1)^2}{e^{\frac{x}{\tau p^*}} - 1} \right],
\] (D4)

where

\[
\gamma_{k}^{Be,0} = \frac{3 \hbar |k|^5}{640\pi m \rho_0}
\] (D5)

is the Beliaev damping constant at zero temperature. To obtain equation [D4], we assumed that the quotient of the atom density of the BEC and total atom density including the thermal cloud is close to one. This is the case for temperatures much smaller than the critical temperature of the BEC [76].

In [40], the effect of Landau damping and Beliaev damping has been investigated and a master equation for the quasi-particle field’s state has been derived that is very similar to the one we obtained for three-body loss here. The difference is modified damping constants and an additional term that corresponds to the inverse process of the second term in equation (16), in which a quasi-particle in mode \(n\) is created from the condensate. For this term to be present, there has to be a bath of quasi-particles that can interact in the inverse processes of Landau and Beliaev damping. Therefore, this is an effect of finite temperature. In particular, it leads to thermalization of the modes. In contrast, for the three-body loss process, we assumed that molecules and highly excited atoms are removed from the system quickly enough to consider the corresponding sectors as baths in the vacuum state, i.e. zero temperature. Therefore, the additional term in the master equation obtained in [40] does not appear here.

On the level of Gaussian states, combining all processes leads to a modification of the constants \(\gamma_k^0\) and \(\gamma_k^s\), where \(\gamma_k^0\) contains the spontaneous and stimulated annihilation processes and \(\gamma_k^s\) contains the creation processes due to the baths. Then, the time evolution including three-body loss, Beliaev damping and Landau damping is still given by equation (D4). Assuming thermal baths with delta correlations for Beliaev and Landau damping, we may write \(\gamma_k^w = |a_k|^2 \gamma_{3b} + (\bar{N}_k + 1)(\gamma_L + \gamma_B)\) and \(\gamma_k^c = |b_k|^2 \gamma_{3b} + \bar{N}_k(\gamma_L + \gamma_B)\), where \(\bar{N}_k\) is the average thermal occupation number of the mode \(k\) and \(\gamma_L\) and \(\gamma_B\) are the single particle (temperature-dependent) damping constants of Landau damping and Beliaev damping, respectively. For this case, we find \(\gamma_k^- = \gamma_{3b} + \gamma_L + \gamma_B\) and \(\gamma_k^+ = (2|a_k|^2 - 1)\gamma_{3b} + (2\bar{N}_k + 1)(\gamma_L + \gamma_B)\).

**FIG. 3.** Total damping constant \(\gamma_k^-\) (blue solid line) and the total noise constant \(\gamma_k^+\) (green dashed line) are plotted as functions of \(|k|L/\pi\), where \(L\) is the length of the elongated direction of the cuboid BEC, based on the parameters mentioned in the text. For low momenta, the \(k\)-independent \(\gamma_{3b}\) due to three-body loss dominates. For higher quasi-particle momenta, Beliaev damping starts to dominate due to its proportionality to \(|k|^5\). In the presented regime of very low temperatures, Landau damping is completely suppressed. The difference between \(\gamma_k^-\) and \(\gamma_k^+\) is strongly pronounced for small momenta where \(|a_k|\) becomes large.
In the following, we will give a few numbers for the damping constants and compare to the effect of three-body loss in different regimes. For an elongated cuboid BEC of length $L = 200 \mu m$ and aspect ratio $1/3$, a number of $N_a = 10^7$ atoms corresponds to a density of $10^{13} \text{cm}^{-3}$ corresponding to $\gamma_{3b} = 0.2 \text{s}^{-1}$ and a speed of sound $c_0 \approx 6 \times 10^{-4} \text{ms}^{-1}$ for Rb. We assume a very low temperature of 200 pK. Then, we find $\gamma_{La}^a \approx 5 \times 10^{-6} |k| L/\pi \text{s}^{-1}$ and $\gamma_{Be}^a \approx 1 \times 10^{-8} |k| L/\pi \text{s}^{-1}$ for a BEC of Rb-atoms. This means that Landau damping is completely suppressed and Beliaev damping is suppressed for small quasi-particle momenta. The total damping constant $\gamma_k^-$ and the total noise constant $\gamma_k^+$ are shown in Figure 3.
