Cubane electrochemistry: direct conversion of cubane carboxylic acids to alkoxy cubanes using the Hofer–Moest reaction under flow conditions

Diego E. Collin, Ana A. Folgueiras-Amador, Derek Fletcher, Mark E. Light, Bruno Linclau, and Richard C. D. Brown

Abstract: The highly strained cubane system is of great interest as a scaffold and rigid linker in both pharmaceutical and materials chemistry. We demonstrate the first electrochemical functionalisation of cubane by oxidative decarboxylative ether formation (Hofer–Moest reaction). The mild conditions are compatible with the presence of other oxidisable functional groups, and the use of flow electrochemical conditions allows straightforward upscaling.

First synthesised in the 1960's, and originally proposed as 3D benzene bioisostere in the 1990's, it is only in the past decade that cubanes have gained real traction in medicinal chemistry. Substituting a phenyl ring by a cubyl unit can lead to improved physical and biological properties. In addition, 1,4-disubstituted cubanes have applications as non-aromatic rigid spacers in organic materials and polymers.

The only practical large-scale synthesis of cubane to date leads to 1,4-cubanedicarboxylic acid, and while cubane functionalisation has been extensively investigated, it has relied heavily on interconversions of the carboxylic acid functional group or indirect decarboxylative functionalisations (Scheme 1). To the best of our knowledge, the only direct decarboxylative cubane C–C bond formation is a single example of Pb(OAc)₄-mediated Kochi coupling reported by Moriarty (Scheme 1). More generally, Redox-Active Esters (RAE), such as the N-phthalimido Kochi coupling reported by Moriarty (Scheme 1). Baran also showed RAE’s as intermediates for Giese radical reactions (not shown), and they have been employed for decarboxylative cubyl-heteroatom bond formation (e.g. decarboxylative borylation, 3–5). Other examples of decarboxylative radical-based methods have been reported.

The synthesis of alkoxy cubanes 7 has been reported from the iodide 6, which is again accessed from cubane carboxylic acids, or their pyridyl esters. Eaton reported that photolysis of a dilute (0.03 M) solution of 1,4-diiodocubane in methanol afforded 1,6-dio-4-methoxycubane in 10% yield. Subsequently, Irngartinger and later Williams improved the efficiency with photolysis yields up to 58%, providing access to methoxycubanes as anisole isosteres.

The viability of processes proceeding via the intermediacy of cubyl radicals is amply supported by the examples described above. Additionally, the possibility of forming cubyl cations is inferred from solvolyses of corresponding iodide or triflate. This precedent, together with our ongoing interest in the area of electrochemically transformed cubane carboxylic acids to alkoxy cubane 7 under flow conditions as a convenient method for cubane to give a variety of ethers. Furthermore, the scalability of the process is demonstrated.

Abstract: The highly strained cubane system is of great interest as a scaffold and rigid linker in both pharmaceutical and materials chemistry. Abstract: The highly strained cubane system is of great interest as a scaffold and rigid linker in both pharmaceutical and materials chemistry. We demonstrate the first electrochemical functionalisation of cubane by oxidative decarboxylative ether formation (Hofer–Moest reaction). The mild conditions are compatible with the presence of other oxidisable functional groups, and the use of flow electrochemical conditions allows straightforward upscaling.

First synthesised in the 1960's, and originally proposed as 3D benzene bioisostere in the 1990's, it is only in the past decade that cubanes have gained real traction in medicinal chemistry. Substituting a phenyl ring by a cubyl unit can lead to improved physical and biological properties. In addition, 1,4-disubstituted cubanes have applications as non-aromatic rigid spacers in organic materials and polymers.

The only practical large-scale synthesis of cubane to date leads to 1,4-cubanedicarboxylic acid, and while cubane functionalisation has been extensively investigated, it has relied heavily on interconversions of the carboxylic acid functional group or indirect decarboxylative functionalisations (Scheme 1). To the best of our knowledge, the only direct decarboxylative cubane C–C bond formation is a single example of Pb(OAc)₄-mediated Kochi coupling reported by Moriarty (Scheme 1). More generally, Redox-Active Esters (RAE), such as the N-phthalimido Kochi coupling reported by Moriarty (Scheme 1). Baran also showed RAE’s as intermediates for Giese radical reactions (not shown), and they have been employed for decarboxylative cubyl-heteroatom bond formation (e.g. decarboxylative borylation, 3–5). Other examples of decarboxylative radical-based methods have been reported.

The synthesis of alkoxy cubanes 7 has been reported from the iodide 6, which is again accessed from cubane carboxylic acids, or their pyridyl esters. Eaton reported that photolysis of a dilute (0.03 M) solution of 1,4-diiodocubane in methanol afforded 1,6-dio-4-methoxycubane in 10% yield. Subsequently, Irngartinger and later Williams improved the efficiency with photolysis yields up to 58%, providing access to methoxycubanes as anisole isosteres.

The viability of processes proceeding via the intermediacy of cubyl radicals is amply supported by the examples described above. Additionally, the possibility of forming cubyl cations is inferred from solvolyses of corresponding iodide or triflate. This precedent, together with our ongoing interest in the area of electrochemically transformed cubane carboxylic acids to alkoxy cubane 7 under flow conditions as a convenient method for cubane to give a variety of ethers. Furthermore, the scalability of the process is demonstrated.
acids were facilitated through the application of flow electrolysis cells.[29] Interest in laboratory electrolysing in continuous flow has grown significantly over the last decade[30] and presents some advantages compared to batch electrolysis. In flow cells, the electrode surface to reactor volume ratio is much higher than in batch, facilitating higher productivity and more efficient mass transfer. Moreover, the interelectrode gap is usually small (typically between 0.1–1 mm), allowing a low loading or even elimination of supporting electrolyte.[31]

For initial exploration of the reactivity of the cubane moiety towards electrolysis, and whether radical or carbocation reactivity would be observed, cubane carboxylic acid 1 was subjected to typical Kolbe-type electrolysis conditions in an undivided flow reactor.[32] Partial deprotonation using KOH as base and excess current (6.2 F) was applied in MeOH, using Pt as anode material.[33] Without supporting electrolyte, preliminary experiments established that 0.5 equivalents of base was required to reach the desired cell current and methyl 4-methoxy-1-cubanecarboxylate (7) was obtained in 14% as the major product (Table 1, entry 1). In addition, starting material 1 (50%) and a small amount of the hydrogenolysis product 10 (<5%) were observed. This promising initial result showed that the cubane ring itself is clearly compatible with anodic oxidation, and that processes proceeding through cubane carbocation formation are viable.

Optimisation efforts continued using Pt and carbon-based anodes (see SI for details). For the Pt anode, it was observed that the presence of supporting electrolytes such as Et4NBF4 and perchlorate salts (from NaClO4, LiClO4) suppressed decarboxylation of cubane, with only traces of 7 observed. Interestingly, while basic conditions are required to form the carbonyl, addition of acetic acid resulted in a significantly improved yield of 40% (entry 2). As anticipated, the corresponding acetoxycubane 8 and the cross-Kolbe product 9 were observed as minor byproducts in the crude reaction mixtures. However, the addition of an excess of acetic acid was not found to significantly increase the formation of 8 and 9.

Doubling the flow rate and maintaining the amount of charge (0.4 mL min⁻¹, 400 mA (6.2 F)) led to the isolation of product 7 in 36% yield in a gramme-scale reaction, along with the formation of the reported byproducts (entry 3). However, attempts to use other alcohols as nucleophiles were hampered by poor solubility of the inorganic base, limiting further development of these conditions. While heterogeneous solutions can be used in a batch electrochemical setup,[34] such approach is not desirable in a flow system. Hence, the use of an organic base was explored, with Et4N affording the best results leading to 7 in 44% yield (entry 4).[35] Omitting acetic acid led to reduced conversion and only 8% of the desired product (entry 5).

Carbocation formation is reported to be favoured using carbon anodes under basic conditions with added perchlorate salts as supporting electrolyte.[37] In the current work, exchanging the Pt anode for a carbon material (C/PVDF, carbon polyvinylidene fluoride composite) under the previously optimised conditions, resulted in a reduced yield of 7 (12%, entry 6) alongside decomposition products (IC H NMR analysis). However, decreasing the applied charge to 2.5 F gave an elevated yield (44%) of the methyl ether 7 (entry 7), and omission of AcOH achieved a further improvement to 52% (entry 8). Significantly, anodic oxidation using the C/PVDF anode, 200 mA (2.5 F) and 0.5 mL min⁻¹ allowed for the formation of 7 with increased productivity and substantially improved current efficiency (42% compared to 14% at Pt).

### Table 1. Selected electrolysis optimisation conditions.

| entry | anode | conditions | flow rate [mL min⁻¹] | current (charge) | RSM [%] | yield [%] |
|-------|-------|------------|---------------------|-----------------|---------|----------|
| 1     | Pt    | KOH        | 0.2                 | 200 mA (6.2 F)  | 50      | 14       |
| 2     | Pt    | KOH, AcOH  | 0.2                 | 200 mA (6.2 F)  | none    | 40       |
| 3     | Pt    | KOH, AcOH  | 0.4                 | 400 mA (6.2 F)  | none    | 36[6]    |
| 4     | Pt    | Et4N, AcOH | 0.2                 | 200 mA (6.2 F)  | none    | 44       |
| 5     | Pt    | Et4N       | 0.2                 | 200 mA (6.2 F)  | 82      | 8        |
| 6[6]  | C/    | Et4N, AcOH | 0.2                 | 200 mA (6.2 F)  | none    | 12       |
| 7[6]  | C/    | Et4N, AcOH | 0.5                 | 200 mA (2.5 F)  | none    | 44       |
| 8     | C/    | Et4N       | 0.5                 | 200 mA (2.5 F)  | none    | 52       |
| 9     | C/    | Et4N       | 0.25                | 200 mA (5.0 F)  | none    | 24       |
| 10[6] | C/    | Et4N, NaClO4| 0.5                | 200 mA (2.5 F)  | 32      | 4        |
| 11[6] | C/    | Et4N, Et4NBF4| 0.5              | 200 mA (2.5 F)  | 20      | 12       |
| 12    | C/    | DBU        | 0.5                 | 200 mA (2.5 F)  | none    | 34       |
| 13[6] | C/    | Et4N       | 0.5                 | 200 mA (2.5 F)  | 22      | 36       |

General conditions: 0.25 mmol of 1, MeOH (5 mL), c = 0.1 M. Determined using calibrated GC.[6] Yield of 7 determined using calibrated GC.[13] AcOH (1.0 eq.).[6] Isolated yield: 1.03 g of 1 gave 350 mg of 7.[6] 5 mM of supporting electrolyte.[13] Et4N (0.75 equiv.). RSM: Remaining Starting Material.

Decreasing the flow rate, while maintaining the same cell current (double amount of charge, 5.0 F), also gave a decreased yield of 24% (entry 9), highlighting the potential for overoxidation of the methoxylated product 7. This was confirmed by resubmitting the reaction mixture containing 7 to the electrolysis conditions, resulting in a decreased yield of 30% (from 50% with one pass through the reactor). Different bases and supporting electrolytes...
were explored (entries 10–13 and SI), but the yield was not improved further, and the presence of NaClO₄ or Et₄NBF₄ retarded decarboxylation.

With optimised conditions in hand, we explored different alcohols as nucleophiles (Figure 1). A range of alkoxylated products from alcohols with different steric hindrance were successfully synthesised (7, 11–13). This included deuterated ethers, illustrated by the synthesis of methyl 4-methoxy(d₅)-1-cubanecarboxylate (11) in 40% yield. The corresponding crystal structure was obtained (see SI, Section 10.4). Selectively deuterated substrates are of interest for medicinal chemistry studies, where the use of deuterium has shown, in some cases, to improve the pharmacokinetic properties.[54] Furthermore, fluorinated cubane ethers (14 and 15) were obtained in moderate to good yields from TFE (2,2,2-trifluoroethanol) and HFIP (1,1,1,3,3,3-hexafluoroisopropanol). The application of fluorinated alcohols was not viable using the C/PVDF anode, which swells in fluorinated solvents (see SI, Section 3.5.3), but was possible using a Pt anode. Other sources of carbon that could be used with fluorinated solvents, such as glassy carbon,[13] showed inferior results for this particular reaction.

The substrate scope was further explored using different functional groups on the cubane moiety, with attention to potential chemoselectivity issues including oxidation of C—H bonds adjacent to nitrogen in amides.[56] Pleasingly, oxidation of the carboxylate occurred in preference, leading to compounds 16–19 in good yields (48–60%). Piperidine (e.g. 16) and morpholine rings (e.g. 19) remained unchanged, offering interesting potential scaffolds for application in drug discovery. Benzyl ethers, which are susceptible to anodic oxidation, were also tolerated albeit with the desired decarboxylative coupling product 20 obtained in a reduced 20% yield. Gratifyingly, the presence of a free alcohol in the molecule did not disturb the electrochemical transformation and compound 21 was obtained in 46% yield as the main product. However, while a t-butyl ester is compatible with the reaction conditions (22, 41%), a Boc-protected amine with or without the base of use did not lead to the desired electrolysis product 23, and starting material was recovered.

To demonstrate the ease of laboratory scale-up using the flow electrolysis approach described herein, 12.5 mmol of starting material was successfully oxidised using the same reactor, giving 1 gramme of pure methoxy-cubane 7 in only 4 h (Scheme 2). While, on a small scale, the formation of methyl 1-cubanecarboxylate 10 as hydrolysis byproduct is insignificant, on gramme-scale ~150 mg of 10 was isolated.

It is worth noting that applying similar conditions in a batch-type cell (similar geometry to commercial batch reactors), compound 7 was obtained in 50% yield. However, 3 h of electrolysis time was required instead of 10 minutes in flow for the same scale (0.5 mmol), and a considerably increased amount of charge (4.0 F) was applied in order to achieve full conversion (see SI, Section 5).

The demonstration of a one-step Hofer-Moest process in flow making 7 accessible on gramme-scale, opens up possible applications of 7 as primary building block for the synthesis of methoxylated phenyl bioisosteres. Cubanisidine 25 was identified as a bioisostere of the highly electron rich and relatively toxic p-anisidine 26 (Scheme 3), and its synthesis was undertaken. Saponification of ester 7 gave 4-methoxycubane carboxylic acid 24 in 94% yield, which was followed by Yamada–Curtius rearrangement to give the corresponding Boc-amine 23 in 69% yield. Cleavage of the carbamate protecting group delivered 4-methoxy-1-cubanamine as its hydrochloride salt 25.

As a further illustrative example, following Williams’ synthesis of a number of pravadoline analogues featuring anisole bioisosteres,[21] the cubane derivative of the synthetic drug anisindione (30) was investigated. Anisindione (30), known under the brand name Miradon,[4] is used as an anticoagulant. 4-Methoxy 1-cubanecarboxylic acid (24) was reduced to 4-methoxy-1-cubanemethanol in 82% yield, and subsequent
oxidation to the corresponding aldehyde 27 was achieved using Dess-Martin periodinane (DMP). Finally, a condensation reaction\(^\text{[9]}\) of 4-methoxy-1-cubanecarbaldehyde (27) and phthalide 28 using NaOMe in EIOAc gave the desired cubanisidine 29 in 33% yield. The use of this condensation reaction involving cubanes will be of great interest in medicinal and materials chemistry, with great promise for further developments. Further applications are under investigation in our laboratories.

In conclusion, to the best of our knowledge, we report the first electrochemical cubane ring system functionalization, through a Hofer-Moest oxidative decarboxylative ether formation. Successful investigation of the substrate scope involving potentially electrochemical oxidisable functionalities clearly indicates the mildness of the reaction conditions. The use of flow electrolysis facilitates laboratory scale-up, as shown by a gramme-scale synthesis in a matter of hours in the same reactor and under the same conditions, nicely demonstrating the advantage of this approach. A further straightforward 3-step process provided a cubanisidine biosiostere building block, and another example of a methoxy-cubane analogue of a drug is described. Organic electrosynthesis is considered as a sustainable methodology, since electrical current replaces potentially hazardous/toxic and costly chemical reagents, and any ensuing waste stream.\(^{[65]}\) This is clearly shown here, with facile access to the methoxy-cubane core from the commercially available 1 by only using methanol as solvent and triethylamine (0.5 equiv.) as reagent. No supporting electrolytes were required, facilitating purification. Hence, this first demonstration of an electrochemical reaction involving cubanes will be of great interest in medicinal and materials chemistry, with great promise for further developments. Further applications are under investigation in our laboratories.

Oxidative anodic decarboxylation of cubane carboxylic acids leading to cubyl ethers is described. This first direct electrochemical functionalisation at the cubane system is chemoselective, and scalable, with yields of up to 60%.

Diego E. Collin, Ana A. Folgueiras-Amador, Derek Pletcher, Mark E. Light, Bruno Linclau, and Richard C. D. Brown*
