1 Department of Geriatrics, First Affiliated Hospital of Nanjing Medical University, Nanjing, China, 2 Clinical Research Center, First Affiliated Hospital of Nanjing Medical University, Nanjing, China, 3 Department of Cardiology, First Affiliated Hospital of Nanjing Medical University, Nanjing, China, 4 Department of Intensive Care Unit, Baoding First Central Hospital, Baoding, China, 5 Department of Geriatrics, Nanjing General Hospital, Nanjing, China, 6 Department of Physiology, University of Cincinnati, Cincinnati, OH, United States

Background: Presence of the β3-Adrenergic receptor (ADRB3) gene Trp64Arg (T64A) polymorphism may be associated with an increased susceptibility for essential hypertension (EH). A clear consensus, however, has yet to be reached.

Objective and methods: To further elucidate the relationship between the ADRB3 gene Trp64Arg polymorphism and EH, a meta-analysis of 9,555 subjects aggregated from 16 individual studies was performed. The combined odds ratios (ORs) and their corresponding 95% confidence intervals (CI) were evaluated using either a random or fixed effect model.

Results: We found a marginally significant association between ADRB3 gene Trp64Arg polymorphism and EH in the whole population under the additive genetic model (OR: 1.200, 95% CI: 1.00–1.43, P = 0.049). Association within the Chinese subgroup, however, was significant under allelic (OR: 1.150, 95% CI: 1.002–1.320, P = 0.046), dominant (OR: 1.213, 95% CI: 1.005–1.464, P = 0.044), heterozygous (OR: 1.430, 95% CI:1.040–1.970, P = 0.03), and additive genetic models (OR: 1.280, 95% CI: 1.030–1.580, P = 0.02). A significant association was also found in the Caucasian subgroup under allelic (OR: 1.850, 95% CI: 1.260–2.720, P = 0.002), dominant (OR: 2.004, 95% CI: 1.316–3.052, P = 0.001), heterozygous (OR: 2.220, 95% CI: 1.450–3.400, P = 0.0002), and additive genetic models (OR: 2.000, 95% CI: 1.330–3.010, P = 0.0009).

Conclusions: The presence of the ADRB3 gene Trp64Arg polymorphism is positively associated with EH, especially in the Chinese and Caucasian population. The Arg allele carriers of ADRB3 gene Trp64Arg polymorphism may be at an increased risk for developing EH.

Keywords: ADRB3, Trp64Arg, polymorphism, essential hypertension, rs4994
INTRODUCTION

Essential hypertension (EH) is a frequently-occurring condition that is associated with an increased risk of atherosclerosis, stroke, heart failure, and kidney failure (Ding et al., 2018; Omisore et al., 2018; Owolabi et al., 2018). These two factors combined, EH presents a significant barrier to health. The genetic epidemiological studies show that EH is a hereditary disease caused by the interplay of multiple genes and the environment. To explore the pathogenesis of EH, researchers are employing techniques from molecular biology to analyze potential genes that may act as risk factors and many believe the ADRB3 to be a strong candidate (Kawaguchi et al., 2006).

The β3-adrenergic receptor (β3-AR, ADRB3) is an important component of sympathetic nervous system that primarily mediates lipolysis and thermogenic function. When the receptor is excited, lipolysis is increased locally. Mutation of the ADRB3 gene can either reduce gene expression on the cytomembrane gene expression or cause an abnormal protein conformation that impairs ADRB3 function. The reduced cellular signal transduction from the repair which prevents adipose tissue heat production and decomposition can contribute to the pathogenesis of multiple conditions, including EH, diabetes mellitus (DM), and obesity.

Human ADRB3 gene, located in 8p11.1–p12, contains 2 exons and 1 intron and encodes 408 amino acids. Mutation of the thymine in the 190th place to cytosine changes the 64th amino acid tryptophan (Trp) into an arginine (Arg) residue in the first intracellular loop of the ADRB3 receptor. This mutation is associated with a ten-fold decrease in adipocyte receptor sensitivity. The Trp64Arg (rs4994) variant is located in the first intracellular loop which is crucial for both the movement and effector function of this receptor. The ADRB3 Trp64Arg variant acts as a “thrifty” gene and has already been associated with obesity, DM, and insulin resistance (IR) (Hoffstedt et al., 1999).

Though many studies on the relationship between ADRB3 gene Trp64Arg polymorphism and EH have been performed, a consensus has yet to be reached. In 2001, Wang et al. found a positive association in a Chinese Beijing population with the 64Arg allele acting as a risk factor for EH (Wang Y. et al., 2001). In 2000, Ringel et al. found the same result in a German population (Ringel et al., 2000). However, other papers reported no significant association in a Beijing and Hong Kong Chinese population (Thomas et al., 2000; Liu et al., 2015). While in 2005, Masuo et al. found the 64Trp allele is candidate allele for EH in a Japanese population (Masuo et al., 2005).

To explore the association of ADRB3 gene Trp64Arg polymorphism and EH, we conducted a meta-analysis of 5,088 EH patients and 4,467 controls from 16 separate studies to evaluate the relationship of ADRB3 gene Trp64Arg polymorphism and EH (Supplementary Table 1).

MATERIALS AND METHODS

Publication Search and Inclusion Criteria
The electronic databases PubMed, the Wan Fang database, the VIP database, the China National Knowledge Infrastructure, the China Biological Medicine Database, Embase, and the Web of Science were searched using the terms “β3-Adrenergic receptor,” “ADRB3,” “Trp64Arg,” “essential hypertension” and “polymorphism.” The publication years ranged from 1997 to 2015 with the most recent update occurring on March 3, 2018.

TABLE 1 | Characteristics of the investigated studies of the association between β3-Adrenergic receptor (ADRB3) gene Trp64Arg polymorphism and essential hypertension (EH).

| Author/Year | Region | Genotype | EH | Control | Matching criteria | SAMPLE size (EH/control) |

HDL, high density lipoprotein-cholesterol; BP, blood pressure; TG, triglyceride; LDL, low density lipoprotein-cholesterol; BMI, body mass index; PCR-RFLP, Polymerase chain reaction-restriction fragment length polymorphism; Case-control study design was adopted in the above studies.
The selected studies evaluated on the following criteria: (a) Evaluation of the relationship of EH and ADRB3 gene Trp64Arg polymorphism. (b) EH diagnosis by a systolic BP no <140 mmHg and a diastolic BP no <90 mmHg measured three times on different days after the secondary hypertension was excluded. (c) The included studies should be case-controlled or officially published cohort studies. (d) The genotype number of ADRB3 gene Trp64Arg polymorphism in the control group should follow the Hardy-Weinberg equilibrium (HWE).

**Data Extraction**

The data was extracted using a standardized protocol carried out by three investigators. Two were responsible for searching for duplicates among individual while the third one acting as an arbiter to settle differences. The studies violating the inclusion criteria, published repeatedly, or providing inadequate data were rejected. Similar data appeared in different papers by the same author group was adopted only once. The following items as publication year, ethnicity, region, the first author's name, genotyping method, matching criteria, genotype number, and total number of cases and controls should be included in the listed data table.

**Statistical Analyses**

Six genetic models were used in the current meta-analysis: allelic (A allele distribution frequency), recessive (AA vs. TA+TT), dominant (AA+TA vs. TT), homozygous (AA vs. TT), heterozygous (TA vs. TT), and additive (T vs. A) genetic models. The odds ratios (ORs) and their corresponding 95% confidence intervals (CIs) were used to compare the relationship of ADRB3 gene Trp64Arg polymorphism and EH. The heterogeneity (HTG) among the individual studies was calculated by using a chi-square-based Q-tests with the significance set at $P < 0.05$ level (Cochran, 1968). The random-effects model (DerSimonian and Laird method) would be adopted when the HTG existed among the different studies (DerSimonian and Laird, 1986). If not, the fixed-effect model would be used (the Mantel–Haenszel method) (Mantel and Haenszel, 1959). The pooled OR was assessed by a Z-test with significance set at $P < 0.05$.

The HWE was evaluated by using Fisher’s exact test with significance set at $P < 0.05$ level. Potential publication bias was assessed using a funnel plot. The funnel plot symmetry was evaluated by using Egger’s linear regression test on the natural logarithm scale of the OR with significance set at $P < 0.05$ level (Egger et al., 1997). The statistical analyses were performed by using stata 12.0 (StataCorp, College Station, TX, USA) and Revman 5.0 software.

**RESULTS**

**Studies and Populations**

Information was extracted from a total of 5,088 EH cases and 4,467 controls (Table 1) (Fujisawa et al., 1997; Baba et al., 1998; Tonolo et al., 1999; Ringel et al., 2000; Thomas et al., 2000;
FIGURE 1 | Forest plot of EH associated with ADRB3 gene Trp64Arg polymorphism under an allelic genetic model (distribution of Arg allelic frequency of ADRB3 gene Trp64Arg polymorphism).

FIGURE 2 | Forest plot of EH associated with ADRB3 gene Trp64Arg polymorphism under a recessive genetic model (AA vs. TA+TT).
FIGURE 3 | Forest plot of EH associated with ADRB3 gene Trp64Arg polymorphism under a dominant genetic model (AA+TA vs. TT).

FIGURE 4 | Forest plot of EH associated with ADRB3 gene Trp64Arg polymorphism under a homozygous genetic model (AA vs. TT).
FIGURE 5 | Forest plot of EH associated with ADRB3 gene Trp64Arg polymorphism under a heterozygous genetic model (TA vs. TT).

FIGURE 6 | Forest plot of EH associated with ADRB3 gene Trp64Arg polymorphism under an additive genetic model (A vs. T).
A significant association under allelic (OR: 1.150, 95% CI: 1.002–1.320, \( P = 0.046 \)), dominant (OR: 1.213, 95% CI: 1.005–1.464, \( P = 0.044 \)), heterozygous (OR: 1.430, 95% CI: 1.040–1.970, \( P = 0.03 \)), and additive genetic models (OR: 1.280, 95% CI: 1.030–1.580, \( P = 0.02 \)). A significant association was also found in Caucasian subgroup under allelic (OR: 1.850, 95% CI: 1.260–2.720, \( P = 0.002 \)), dominant (OR: 2.004, 95% CI: 1.316–3.052, \( P = 0.001 \)), heterozygous (OR: 2.220, 95% CI: 1.450–3.400, \( P = 0.0002 \)), and additive genetic models (OR: 2.000, 95% CI: 1.330–3.010, \( P = 0.0009 \)). (Table 2, Figures 1–6).

Significant HTG was detected under allelic, dominant, heterozygous, and additive genetic models (allelic: \( P_{HTG} = 0.005, I^2 = 55.0\% \)); dominant: \( P_{HTG} = 0.001, I^2 = 59.0\% \)); heterozygous: \( P_{HTG} < 0.00001, I^2 = 80.0\% \)); and additive: \( P_{HTG} < 0.0001, I^2 = 69.0\% \)). Stratification by ethnicity, however, resulted in no significant HTG under the allelic genetic model in the Chinese (\( P_{HTG} = 0.07, I^2 = 43.0\% \)), Japanese (\( P_{HTG} = 0.06, I^2 = 59.0\% \)), or Caucasian subgroups (\( P_{HTG} = 0.69, I^2 = 0\% \)). Stratification significantly decreased in all of the three subgroups under the dominant, (Chinese: \( P_{HTG} = 0.062, I^2 = 44.6\% \)); Japanese: \( P_{HTG} = 0.034, I^2 = 65.3\% \)); and Caucasian subgroup: \( P_{HTG} = 0.718, I^2 = 0\% \)), the heterozygous (Chinese: \( P_{HTG} < 0.0001, I^2 = 76.0\% \)); Japanese: \( P_{HTG} = 0.0005, I^2 = 83.0\% \)); Caucasian subgroup: \( P_{HTG} = 0.740, I^2 = 0\% \)), and the additive genetic model (Chinese: \( P_{HTG} = 0.002, I^2 = 65.0\% \)); Japanese: \( P_{HTG} = 0.01, I^2 = 73.0\% \)); Caucasian subgroup: \( P_{HTG} = 0.71, I^2 = 0\% \)).

Bias Diagnostics

We found no publication bias in the funnel plot under the additive genetic model (Figure 7). In addition, there was no significant difference in the Egger’s test yet, which implied that no publication bias existed in the present meta-analysis under the dominant genetic model (\( T = −0.86, P = 0.975 \)) (Figure 8).

Sensitivity Analysis

The subsequent sensitivity analysis has been performed to observe whether the results are stable. After each study was excluded from the current meta-analysis, the significant was still significant under the additive genetic model (Figure 9).

DISCUSSION

A significant relationship was found in the present meta-analysis between ADRB3 gene Trp64Arg polymorphism and EH under an additive genetic model (OR: 1.200, 95% CI: 1.00–1.43, \( P = 0.049 \)) in the whole population. In the Chinese subgroup, the association was more significant under allelic (OR: 1.150, 95% CI: 1.002–1.320, \( P = 0.046 \)), dominant (OR: 1.213, 95% CI: 1.005–1.464, \( P = 0.044 \)), heterozygous (OR: 1.430, 95% CI: 1.040–1.970, \( P = 0.03 \)), and additive genetic models (OR: 1.280, 95% CI: 1.030–1.580, \( P = 0.02 \)). An increased association was also found in Caucasian subgroup under allelic (OR: 1.850, 95% CI: 1.260–2.720, \( P = 0.002 \)), dominant (OR: 2.004, 95% CI: 1.316–3.052, \( P = 0.001 \)), heterozygous (OR: 2.220, 95% CI: 1.450–3.400, \( P = 0.0002 \)), and additive genetic models (OR: 2.000, 95% CI: 1.330–3.010, \( P = 0.0009 \)).
The fixed model was used for the recessive or homozygous genetic models because no significant heterogeneity was detected ($P_{HTG} > 0.05$). Although there was significant HTG under the allelic, dominant, heterozygous, and additive genetic models ($P_{HTG} < 0.05$), it was reduced significantly when stratified by ethnicities, lending further strength to the positive association between the polymorphism and EH. In addition, the average 64Arg minor allele frequency is 0.16, 0.18, 0.06 in the Chinese, Japanese, and Caucasian populations. The minor allele frequencies of the polymorphism is different across different populations. The lower the minor allele frequency, the more significant the association of this mutation and EH. It might explain why the OR is diluted when assessing the whole sample as compared to only the Chinese or Caucasians. As six genetic models were used, only the analysis using additive genetic model was identified a prior and primary analysis. Other analyses under the allele, recessive, dominant, heterozygous, and homozygous genetic models were listed as secondary analyses.

EH is one of the most common cardiovascular conditions and its morbidity has increased annually in China recently. EH increases a patient's risk of coronary artery disease (CAD), stroke, cardiovascular disease, and renal injury. Among the many risk factors involved in the pathogenesis of EH, IR, and dyslipidemia are likely the most important. EH is almost always accompanied by CAD, obesity, hyperlipemia, and/or DM. Reaven et al. call it X syndrome. The central links are IR and dyslipidemia which are considered to have the common hereditary basis (Reaven and Chen, 1988).

The ADRB3 receptor is widely distributed throughout human adipose tissue. Trp64Arg polymorphism is the only functional variant of ADRB3 protein. It has been found that this polymorphism has a significant influence on peak cAMP levels upon excitement with a selective β-receptor agonist, and receptor down-regulation induced by other agonists (Piétri-Rouzel et al., 1997). The ADRB3 64Arg carriers have the ADRB3 gene expression defects and abnormal ADRB3 protein structure which lead to the decreased ADRB3 protein function. The impaired and inhibited cellular signal transduction caused the decreased visceral fat lipolysis and energy production which contributed to an increased body weight and a reduced basal metabolic rate (Guay et al., 2014; De Luis Román et al., 2017). The body mass was thus increased and the norepinephrine's sensitivity was improved, and the blood pressure was elevated (Baba et al., 1998).

In 2010, the meta-analysis by Kitsios et al. found a significant association for the Trp64Arg variant of the ADRB3 gene and EH only under the dominant model (OR: 1.31, 95% CI: 1.07–1.60), not under the allele contrast model (OR: 1.00, 95% CI: 0.83–1.21) (Kitsios and Zintzaras, 2010). While the Kitsios analysis only included 6 studies or 13 studies in HWE under the allele or dominant respectively, the current meta-analysis included 16 studies in HWE under six genetic models and may therefore present a more objective perspective. In addition, stratification by ethnicity may make this analysis more comprehensive than that by Kitsios et al.

The PRISMA workflow was followed by the current meta-analysis (Page and Moher, 2017). Our analysis, however, does not substitute for a large-scale or prospective study on the relationship of ADRB3 gene Trp64Arg polymorphism and EH. Serum ADRB3 levels can be influenced by a number of factors, such as obesity, DM, and hyperlipemia. The micro-effects of other genes combined may additionally influence an individual's susceptibility for EH. Polymorphisms in other genes, such as angiotensin converting enzyme gene
insertion/deletion polymorphism, α-Adducin Gly460Trp gene mutation, bradykinin β2 receptor−58T/C gene polymorphism, TNF-α G308A gene polymorphism may additionally influence the EH susceptibility (Li, 2012a,b; Li et al., 2012; Li Y., 2012).

In brief, ADRB3 gene Trp64Arg polymorphism was significantly correlated with increased EH risk, especially in the Chinese and Caucasian population. Carriers of the Arg allele of ADRB3 gene Trp64Arg polymorphism may be at an increased risk of EH. This conclusion maybe helpful in the formulation of a novel personalized EH treatment approach. Considering the limitations mentioned above, more researches on the association of ADRB3 gene Trp64Arg polymorphism and EH are needed to further confirm the conclusions.

ACKNOWLEDGMENTS
This work was funded by the National Natural Science Foundation of China (NSFC 81100073 to YL), Excellent Young and Middle-Aged Teachers Assistance Program of Nanjing Medical University for YL (2013–2015, JX2161015034) and the Priority Academic Program Development of Jiangsu Higher Education Institutions (PAPD). This work was also funded by the Natural Science Foundation of Jiangsu Province (BK 2012648 to HW), six talent peaks project in Jiangsu Province (2015-WSN-033). Thank all our colleagues working in the First Affiliated Hospital of Nanjing Medical University.
