Abstract
Background: Vitrectomy with internal limiting membrane (ILM) peeling is an effective surgical procedure for the treatment of macular holes (MHs). However, there is a possibility of poor postoperative anatomical closure with conventional ILM peeling for MHs larger than 400 μm. Therefore, a novel inverted ILM flap technique was developed for such cases.

Objectives: This meta-analysis study was performed to evaluate and compare the anatomical and visual outcomes of the inverted ILM flap technique and ILM peeling in large MHs.

Methods: The Cochrane Library, PubMed, and Embase databases were searched to identify randomized controlled trials (RCTs). The trial eligibility and risk of bias were assessed according to Cochrane review methods. The primary outcome measures included MH closure rate and postoperative visual acuity (VA). Subgroup analysis of postoperative VA based on follow-up time was also conducted. Pooled odds ratios (ORs), weighted mean difference (WMD), and 95% confidence intervals (CIs) were calculated. Statistical analysis was performed using RevMan 5.3 software.

Results: Five RCTs with a total of 155 eyes in the inverted ILM flap group and 161 eyes in the ILM peeling group were included in this meta-analysis. Statistical meta-analysis revealed that the overall MH closure rate in the inverted ILM flap group was significantly higher than that in the ILM peeling group (OR = 3.10; 95% CI: 1.25–7.66; p = 0.01). The postoperative VA was significantly better in the inverted ILM flap group than the ILM peeling group (WMD = −0.14; 95% CI: −0.21 to −0.07; p = 0.0002). The subgroup meta-analysis indicated that the postoperative VA was significantly better in the inverted ILM flap group than the ILM peeling group (WMD = −0.17; 95% CI: −0.26 to −0.08; p = 0.0004) at the 3-month follow-up. However, no significant difference was observed between the 2 groups at the 6-month follow-up (WMD = −0.09; 95% CI: −0.20 to 0.02; p = 0.10).

Conclusions: Vitrectomy with the inverted ILM flap technique showed a higher anatomical closure rate as well as visual gain – although only in the short term as no difference in visual recovery was found at the 6-month follow-up – than did ILM peeling in large MHs. The inverted ILM flap technique should be considered as a preferred and routine procedure for the treatment of patients with MHs larger than 400 μm.

Introduction

Macular holes (MHs) are anatomical defects in the fovea of retina characterized by the interruption of neural retinal layers from the internal limiting membrane (ILM) to the photoreceptor layer. This can cause blurred and distorted central vision and occurs more frequently in women over the age of 50 years [1, 2]. Vitrectomy was first described by Kelly and Wendel [3] and is considered the most effective surgical procedure for the treatment of MHs. Although internal limiting membrane (ILM) peeling is performed during surgery, the anatomical success rate of surgery is not consistent for different sizes of MHs. The size of MH affects the healing rate. Previous studies reported that the success rate of MH surgery is 91–98% for MHs <400 μm [4–6]. However, the anatomical success rate of MHs larger than 400 μm can be as low as 50–80% [7–9]. Therefore, a novel inverted ILM flap technique was developed for the treatment of large MHs [10].

Although studies suggest that the inverted ILM flap technique achieves better anatomical and visual outcomes compared to ILM peeling [11–13], some studies have shown that the outcomes of the inverted ILM flap technique in large MHs is statistically similar to that observed in conventional ILM peeling [8, 14–16]. At present, a meta-analysis using randomized controlled trials (RCTs) to compare anatomical and visual outcomes between the 2 methods in MHs larger than 400 μm has not been published. Therefore, we performed a meta-analysis of RCTs to evaluate the efficacy of vitrectomy with the inverted ILM flap technique to determine if it has high closure rates and good improvements in visual acuity (VA) for large MHs.

Methods

Search Strategy

This meta-analysis was conducted in accordance with the Cochrane Handbook for Systematic Reviews of Interventions and Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) Statement. The PRISMA 2009 Checklist is presented in online suppl. Material 1 (for all online suppl. material, see www.karger.com/doi/10.1159/000515283). An electronic search of PubMed, Embase, and Cochrane Library until June 7, 2020, was performed to identify relevant studies. The following terms were used for the searches: “macular hole,” “inverted internal limiting membrane flap,” “inverted ILM flap,” “inverted flap,” “internal limiting membrane peeling,” “ILM peeling,” and “standard ILM peel.” The literature search results were imported into a reference management software (EndNote X4; Thomson Reuters, New York, NY, USA), and duplicate reports were deleted. Afterward, 2 evaluators (Y.X. and J.-G.Y.) read the titles and abstracts to eliminate irrelevant reports. Subsequently, the remaining reports were reviewed by reading the full text to determine if they met the inclusion criteria. In addition, their reference lists were also searched for additional articles.

Inclusion and Exclusion Criteria

The studies were included if they met the following criteria: (1) studies must be RCTs, (2) studies must compare inverted ILM flap technique and ILM peeling, (3) studies should include patients with MHs larger than 400 μm, (4) studies should report the anatomical hole closure rate and VA, and (5) the follow-up duration must be at least 3 months or longer. Exclusion criteria were as follows: (1) studies without the ILM peeling group; (2) studies that compared with other surgeries, such as modified inverted ILM flap techniques; (3) the data could not be used for meta-analysis; (4) studies that included patients with macular retinoschisis or MHs with retinal detachment; and (5) retrospective studies, case reports, and review articles.

Data Extraction

Two reviewers (J.-G.Y. and J.W.) independently extracted the following demographic and clinical data from each of the study: first author, year of publication, study location, study design, number of eyes, mean age, sex, minimum diameter, hole closure rate, and follow-up period. Any discrepancies in data abstraction were resolved via discussion with another author (Y.X.).

Quality Assessment

The quality of the RCTs included was assessed to identify any potential risk of bias using the Cochrane Risk of Bias assessment tool. Seven domains were assessed: (1) random sequence generation, (2) allocation concealment, (3) blinding of participants and personnel, (4) blinding of outcome assessment, (5) incomplete outcome data, (6) selective reporting, and (7) other bias. Each domain was classified into “low risk of bias,” “high risk of bias,” and “unclear risk of bias.” Three reviewers (J.-G.Y., J.W., and Y.X.) independently evaluated the clinical trials using this tool, and discrepancies were resolved via discussion.

Statistical Analysis

Statistical analysis was performed using RevMan software (version 5.3; Cochrane Collaboration, Oxford, UK). For continuous outcomes, the means and standard deviations (SDs) were used to calculate the weighted mean difference (WMD) with 95% confidence intervals (CI). However, odds ratios (ORs) with 95% CI were calculated for dichotomous outcomes. Statistical heterogeneity between studies was assessed using the χ2 test, with p < 0.05 and I2 >50% indicating significant heterogeneity [17]. Heterogeneity was considered low when I2 ≤50%, and the data were analyzed using the fixed-effects model. Instead, the random-effects model was used when I2 >50% [18]. Potential publication bias was examined via visual inspection of a funnel plot [19]. A p value <0.05 was considered statistically significant.

Results

Study Selection

A total of 914 records were identified through a systematic literature search. There were 103 records left after
Records identified through database searching (n = 914)
Additional records identified through other sources (n = 0)
Records after duplicates removed (n = 103)
Records screened (n = 103)
Full-text articles assessed for eligibility (n = 43)
Studies included in qualitative synthesis (n = 5)
Studies included in quantitative synthesis (meta-analysis) (n = 5)
Records excluded based on abstracts (n = 60)
Full-text articles excluded, with reasons (n = 38)
Not RCT studies (n = 15)
Non-comparative study (n = 6)
Compared with other surgeries (n = 9)
Absence of data (n = 8)
Fig. 1. Flowchart of the literature search and selection. RCT, randomized controlled trial.

The duplicates were removed, of which 60 reports were excluded based on the title and abstract. The remaining 43 studies were assessed by reading the full text. Out of the 43 reports, 15 studies were not RCTs, 6 studies were noncomparative studies, 9 studies made comparisons with other surgeries, and 8 studies lacked relevant data. Therefore, these reports were excluded from the meta-analysis. The 5 RCTs that met our inclusion criteria were included in the final meta-analysis [10, 11, 14–16]. The study selection process is shown in Figure 1.

Characteristics of the Studies
The selected studies included a total of 316 eyes, 155 of which were in the inverted ILM flap group and 161 in the ILM peeling group. Two studies were performed in India [11, 14], and one each were performed in Italy [16], Mexico [15], and Poland [10]. All of the studies were published between 2010 and 2018. The age of the patients ranged from 60 to 71 years. The number of eyes examined in the studies ranged from 12 to 51. The characteristics of each study are shown in Table 1, and the risk of bias assessment is shown in Figure 2. Overall, the included studies were at low risk for bias.

Outcomes of Meta-Analysis
Overall MH Closure Rate
The overall MH closure rate was compared between the inverted ILM flap and ILM peeling group across 5 studies. No statistical heterogeneity was found ($I^2 = 0\%$). Therefore, the data were analyzed using the fixed-effects model. The pooled data showed that the MH closure rate in the inverted ILM flap group was significantly higher than that in the ILM peeling group (OR = 3.10; 95% CI: 1.25–7.66; $p = 0.01$) (shown in Fig. 3).

RCT, randomized controlled trial; ILM, internal limiting membrane; nr, not reported.

Fig. 2. Assessment of the risk of bias in included studies. Risk of bias graph: judgments about each “risk of bias” item presented as percentages across all included studies (a); risk of bias summary: the detailed risk of bias values for each article (b). +, low risk of bias; −, high risk of bias; ?, unclear risk of bias.
Preoperative Visual Acuity

There were only 4 studies pooled together to compare the preoperative VA (logMAR units) between 2 groups because one study [10] did not report the SD of the preoperative VA. No statistical heterogeneity was found ($I^2 = 0\%$), and the data were analyzed using the fixed-effects model. The forest plots revealed that the difference in the preoperative VA was not statistically significant between the inverted ILM flap group and the ILM peeling group (WMD = −0.07; 95% CI: −0.15 to 0.01; $p = 0.07$) (shown in Fig. 4a).

![Fig. 3. Forest plots of macular hole closure rate between inverted ILM flap and ILM peeling groups. ILM, internal limiting membrane.](image1)

![Fig. 4. Forest plots of visual acuity (logMAR units) between inverted ILM flap and ILM peeling groups. Preoperative visual acuity (a); postoperative visual acuity (b). ILM, internal limiting membrane.](image2)
Postoperative Visual Acuity

Four studies were pooled together to compare the postoperative VA (logMAR units) between the 2 groups. No statistical heterogeneity was found ($I^2 = 32\%$); hence, the data were also analyzed using the fixed-effects model. Meta-analysis of these data showed that the postoperative VA was significantly better in the inverted ILM flap group than the ILM peeling group ($\text{WMD} = -0.14; 95\% \text{ CI: } -0.21\text{ to } -0.07; p = 0.0002$) (shown in Fig. 4b).

The subgroup analysis of postoperative VA was performed based on the follow-up duration. The follow-up duration was divided into 3 and 6 months. In the subgroup analysis of the follow-up duration at 3 months, 2 studies were pooled together which included 55 eyes from the inverted ILM flap group and 60 eyes from the ILM peeling group. No significant heterogeneity ($I^2 = 0\%$) was found across the studies; thus, the data were analyzed through the fixed-effects model. Meta-analysis of these data showed that the postoperative VA at 3 months was significantly better in the inverted ILM flap group than the ILM peeling group ($\text{WMD} = -0.17; 95\% \text{ CI: } -0.26\text{ to } -0.08; p = 0.0004$) (shown in Fig. 5). In the subgroup analysis of the follow-up duration at 6 months, 2 studies were pooled together, which included 105 eyes from the inverted ILM flap group and 110 eyes from the ILM peeling group. The pooled results did not show any significant difference between the 2 groups at 6 months ($\text{WMD} = -0.09; 95\% \text{ CI: } -0.20\text{ to } 0.02; p = 0.10$) (shown in Fig. 5).

Publication Bias Analysis

The funnel plots showed that the distribution of the plots was symmetric. Most points were distributed in the middle and top of the baseline and were located in the range of the inverted funnel, which indicated that no serious publication bias affected the credibility of this study (shown in Fig. 6).

Discussion

Previous studies reported that vitrectomy with ILM peeling can remove the anteroposterior and tangential tractional forces of the macular retina surface to promote the healing of the hole [20–22]. For MHs smaller than 400 µm, ILM peeling was enough to achieve a high successful anatomic healing rate [23]. However, for MHs larger than 400 µm, conventional ILM peeling was not enough to ensure the successful healing of the hole [24, 25]. This could be due to the distance between the broken ends of the retina that contains large neural defects which are difficult to fill with the proliferation of glial cells alone [14] unless a scaffold was provided for the migration of glial cells. Thus, a novel inverted ILM flap technique was developed for the treatment of large MHs. The current meta-analysis of 5 RCTs showed that the overall MH closure rate of the inverted ILM flap group was significantly higher than that in the ILM peeling group. This suggests that
The inverted ILM flap technique should be considered first and used more often for the treatment of large MHs. The inverted ILM flap technique provides a smooth and gap-free natural scaffold for the proliferation and migration of glial cells [10, 26]. The Muller cells were also activated to secrete neurotrophic factors and basic fibroblast growth factors on the surface of the ILM, which may promote the survival of the retinal neurons and help the photoreceptor cells grow to the center of the fovea [27]. Manasa et al. [11] reported that the ILM flap not only provides a basement membrane for cells to proliferate but also provides an environment for the photoreceptors to align to a new position in direct proximity to the fovea. Moreover, the ILM flap on MHs can create a closed compartment that enables the retinal pigment epithelium to pump out the subretinal fluid effectively. It prevents further leakage of the fluid into the fovea, thereby keeping the hole dry and contributing to MH closure [11]. This may explain the higher anatomical closure rate in the inverted ILM flap group than in the ILM peeling group.

Improved functional outcomes after surgical closures of large MHs may depend on the restoration of the outer retinal layers. MH surgery is expected to result in a type 1 anatomical closure. Type 1 closure is considered the best healing of MH with improved visual function recovery, smaller photoreceptor layer defects, and normal retinal thickness at the end of the follow-up [28]. In previous studies, the inverted ILM flap was reported to have a higher incidence of type 1 closure in large MHs compared to the standard ILM peeling [11]. Thus, the functional outcome should be significantly better in the inverted ILM flap group. This was also consistent with the results of our meta-analysis, which showed that the postoperative VA was significantly better in the inverted ILM flap group than in the ILM peeling group. There was no significant difference in the preoperative VA between the 2 groups, which could have reduced the preintervention effects to postoperative VA.

The subgroup analysis of postoperative VA was based on the follow-up duration to determine the short- and long-term visual efficacy. The results showed that the patients on the inverted flap technique had a significant visual improvement at the 3-month follow-up; however, there was no significant difference between the 2 groups at the 6-month follow-up. It is possible that patients with the inverted ILM flap technique had faster visual recovery during the short-term follow-up of 3 months, which depended on its high MH closure rate. On the other hand, the best-corrected visual acuity in the ILM peeling group continued to show signs of improvement up to 6 months after surgery. During the following months, the following MH healing processes were observed: a proliferation of Muller cells, regeneration of retinal tissue starting from the external limiting membrane, photoreceptor migra-

tion into the retina defect, and reposition, followed by restoration of the ellipsoid-zone layer [29–31]. For as long as the MH healed, the possibility of improved functional outcomes can be obtained.

The inverted ILM flap technique was beneficial to the MH healing; however, after the MH closure, no statistically significant difference in the improvement of the postoperative VA was found upon long-term follow-up regardless of the surgical method used. In addition, it should be understood that the size of the MH affects postoperative MH healing and vision recovery. Furthermore, even with MH closure, the foveal structure did not return to the normal-layered structure of the retina in large MHs [24, 32]. Therefore, no matter which surgical method is used, the visual recovery after vitrectomy is limited at a longer follow-up.

In general, larger MH apertures correlate with worse preoperative VA. When the aperture of the MH is >600 µm, or even >1,000 µm, a large number of photoreceptor cells were apoptotic and damaged. Ooto et al. [33] suggested that the foveal photoreceptor layer in the MH might be destroyed and had irreversible damage. When an MH heals after vitrectomy, the photoreceptor inner segment and outer segment (IS/OS) layer and external limiting membranes would return gradually after surgery, but the normal-layered structure of the outer retina was not restored completely in all cases. Ota et al. [34] demonstrated that the fovea loses its original stratified structure in many cases after a large MH heals. Moreover, preoperative MH apertures may be related to the restoration of the outer retina. No further subgroup comparison of visual recovery for different apertures of large MHs was performed in the included literature. During the long-term follow-up, we found that there was no statistically significant difference in visual recovery between the inverted ILM flap group and the ILM peeling group. While the inverted ILM flap technique has advantages on the inverted ILM flap group and the ILM peeling group. While the inverted ILM flap technique had a better visual recovery in the short-term follow-up. But the advantage of visual recovery could not be found at a longer follow-up. The inverted ILM flap technique had a better efficacy for patients with highly myopic MHs regarding closure rate, foveal microstructure, and postoperative best-corrected visual acuity 6 months after surgery [35, 36], it would be more convincing if the same conclusion can be drawn from a systematic review and meta-analysis of related RCTs, which will be addressed in future studies.

There were some limitations in this study. First, all of the included studies had small sample sizes. Second, follow-up durations in the included studies were not long enough for better observation of VA recovery. Third, the sizes of MHs may affect the closure rate and functional recovery. The closure type may also affect the postoperative VA. Unfortunately, we were not able to perform a subgroup analysis for these variables due to the lack of data. Last, the area of ILM peeling, toxicity of the ILM stain, air or longer-acting gas tamponade, postoperative face-down position, and time may also have influenced the closure rates. However, we were unable to find sufficient data to investigate these parameters. Therefore, more RCTs with larger sample sizes and longer follow-up durations for evaluating the aforementioned parameters are required.

**Conclusion**

This meta-analysis provides evidence that vitrectomy with the inverted ILM flap technique had a higher anatomical closure rate than ILM peeling in large MHs. The ILM flap technique had a better visual recovery in the short-term follow-up, though the advantage of visual recovery was not found at a longer follow-up. The inverted ILM flap technique should be considered as a preferred and routine procedure for the treatment of patients with larger MHs. However, more RCTs with larger sample sizes and longer follow-up durations are recommended to confirm the efficacy of the inverted ILM flap technique.
Statement of Ethics

The research was conducted ethically in accordance with the World Medical Association Declaration of Helsinki. Our research did not include original overview of clinical trials, and this article is a summary analysis of published data. Therefore, ethical approval was not required.

Conflict of Interest Statement

The authors have no conflicts of interest to declare.
