Recent KLOE results on kaon physics

E. Czerwiński on behalf of KLOE–2 Collaboration

Institute of Physics, Jagiellonian University, 30-059 Cracow, Poland

Abstract

A short review of two measurements recently published by KLOE/KLOE–2 collaborations is presented. Namely the most stringent limits of the CPT-violating parameters $\Delta a_\mu$ for neutral kaons, and the absolute branching ratio of $K^+ \rightarrow \pi^+\pi^-\pi^0(\gamma)$ decay. In addition a discussion of starting KLOE–2 project is performed.

Keywords: kaons, kaon decays, CPT symmetry, Lorentz invariance, interferometry, $e^+e^-$ collider

1. Introduction

The K LOng Experiment completed its data taking campaign in 2006. The detector designed for neutral and charged kaons studies operated at the DAΦNE $e^+e^-$ collider [1] with a c.m. energy working point equal to the $\phi$ meson mass, where kaons were produced in pairs from the $\phi$ meson decay (BR($\phi \rightarrow KK$) $\approx 83\%$). Total data sample corresponding to $2.5fb^{-1}$ of integrated luminosity allowed to study discrete symmetries and to precisely measure dominant kaon branching ratios. Recently an upgraded KLOE detector started operation to extend KLOE physics program (KLOE–2).

2. KLOE detection setup

The KLOE system consists mainly of two detectors: a cylindrical drift chamber with diameter of 4m [2] surrounded by an electromagnetic calorimeter [3], both immersed in 0.5T magnetic field. High performance of drift chamber for momentum and vertex reconstruction ($\sigma_p/p < 0.4\%$ for $\theta > 45^\circ$; $\sim 150 \, \mu m$ in transverse plane) and excellent time and energy resolution of the calorimeter ($\sigma_E/E = 57ps/\sqrt{E(GeV)} @ 100GeV$; $\sigma_E/E = 5.7\%/\sqrt{E(GeV)}$) ensure high quality of collected data. The $\phi$ meson produced in $e^+e^-$ collisions has only a small momentum in z direction ($\sim 15MeV$).

Since kaons are always produced in pairs from $\phi$ decay, identification of only one of them allows for four-momentum determination of the second one. This is the so called tagging technique.

3. CPT symmetry and Lorentz invariance test

The CPT symmetry as a simultaneous composition of charged conjugation (C), parity (P) and time reversal (T) appears to be the only respected discrete symmetry in Nature. Tiny CPT symmetry violations might appear in conjunction with Lorentz symmetry breaking [4]. In view of an effective field theory (Standard Model Extension) [5–7] for neutral kaons the CPT violation is introduced in the mixing parameter $\delta_K$, with an additional dependence on the four-momentum of kaon:

$$\delta_K \approx i \sin \phi_{SW} e^{i\beta_K} \gamma_K (\Delta a_0 - \bar{\beta}_K \cdot \Delta a)/\Delta m,$$

where $\gamma_K$ and $\beta_K$ are the boost factor and velocity of the kaon in the observer rest frame, respectively, $\phi_{SW} = \arctan(2\Delta m/\Delta \Gamma)$ is the superweak phase with $\Delta m$ and $\Delta \Gamma$ the differences of mass and width between $K_S$ and $K_L$, respectively, and $\Delta a_0$ are four CPT and Lorentz violating coefficients [5–7]. Determination of these parameters are naturally performed in the reference frame of fixed stars. Since $\phi$ is produced at DAΦNE almost at rest $p_1 \sim -p_2$ and $\delta_K(\vec{p}_1) \neq \delta_K(\vec{p}_2)$, where $\vec{p}_i$ denotes momentum of each kaon. On the other side the
K mesons produced in ϕ meson decays are in a coherent quantum state ($J^{PC} = 1--$) and the initial state can be written as:

$$\langle \mu \rangle = \frac{N}{\sqrt{2}} \left[ |K_S(\mu_1)\rangle |K_L(\mu_2)\rangle - |K_L(\mu_1)\rangle |K_S(\mu_2)\rangle \right],$$

(2)

where $N = \sqrt{(1 + |\epsilon_S|^2)(1 + |\epsilon_L|^2)/(1 - \epsilon_S \epsilon_L)} \approx 1$ is a normalization factor, and $\epsilon_{S,L} = \epsilon_K \pm \delta_K$. The known contribution from CP symmetry violation is introduced as $\epsilon_K$. The experimental observable from the integration of equation (2) over the sum of proper decay times $\tau_1 + \tau_2$ at fixed time difference $\Delta \tau = \tau_1 - \tau_2$ is the following [8]:

$$I_{\mu f}(\Delta \tau) \propto e^{-\Gamma_{\Delta \tau}} \left[ |p_1|^2 e^{i \Delta \Phi_{\Delta \tau}} + |p_2|^2 e^{i \Delta \Phi_{\Delta \tau}} - 2 \text{Re}\left( \eta_1 \eta_2 e^{-i \Delta \Phi_{\Delta \tau}} \right) \right]$$

(3)

where $\eta_1 = \langle f_1 \mid T \mid K_S \rangle / \langle f_1 \mid T \mid K_L \rangle = \epsilon_K - \delta_k (f_1, f_2)$, $f_1$ and $f_2$ denote kaon final states, $\Gamma = \Gamma_S + \Gamma_L$. In the reported measurement $f_1 = f_2 = \pi^+ \pi^-$ and the fully destructive quantum interference at $\Delta \tau = 0$ the distribution is sensitive to changes of $\eta_1/\eta_2$ ratio.

At KLOE the measurement of $\phi \to K_S K_L \to \pi^+ \pi^- \pi^0$ reaction has been performed in order to obtain the $\Delta m_0$ parameters from the fit of equation (3) to experimental data. The selection criteria are based on:

- the invariant mass of the tracks connected to a vertex,
- two-body kinematics,
- missing momentum and energy.

The total contamination of signal is 1.5% mostly from kaons regenerated on the beam pipe, whereas the average signal efficiency is $\sim 25\%$. Taking into account detector localization on Earth as well as rotation and movement of Earth itself the space-time coordinates of selected events are transformed to the sidereal frame. A proper fit of the experimental $I(\Delta \tau)$ distribution yields the following values of the four parameters of Standard Model Extension at KLOE are [9]:

$$\Delta m_0 = (-6.0 \pm 7.7_{\text{stat}} \pm 3.1_{\text{syst}}) \times 10^{-18} \text{GeV},$$

$$\Delta \alpha_1 = (0.9 \pm 1.5_{\text{stat}} \pm 0.6_{\text{syst}}) \times 10^{-18} \text{GeV},$$

$$\Delta \alpha_2 = (-2.0 \pm 1.5_{\text{stat}} \pm 0.5_{\text{syst}}) \times 10^{-18} \text{GeV},$$

$$\Delta \alpha_3 = (3.1 \pm 1.7_{\text{stat}} \pm 0.5_{\text{syst}}) \times 10^{-18} \text{GeV}.$$

At present the reported values are the most precise measurement of these parameters in the quark sector of Standard Model Extension and the first independent measurement of all four parameters in the kaon sector.

4. BR($K^+ \to \pi^+ \pi^- \pi^0(\gamma)$) measurement

The last measurement of BR($K^+ \to \pi^+ \pi^- \pi^0$) was performed in 1972 without information about the radiation cut-off [10] whereas value reported in PDG [11] is obtained from a global fit that does not use any of the available BR($K^+ \to \pi^+ \pi^- \pi^0$) measurements but the rate measurement $\Gamma(\pi^+ \pi^- \pi^0) = (4.511 \pm 0.024) \times 10^6$ s$^{-1}$ published in 1970 [12]. In the $\pi^0 \pi^0$ invariant mass distribution of data collected by NA48 a cusp-like anomaly at $M_{\pi^0} = 2m_{\pi^-}$ can be observed [13]. The interpretation is the final state charge-exchange reaction $\pi^+ \pi^- \to \pi^0 \pi^0$ in $K^+ \to \pi^+ \pi^- \pi^0$ decay [14, 15]. Based on the fit of models [16] and [17, 18] to experimental $M_{\pi^0}$ distribution the difference between the S-wave $\pi \pi$ scattering lengths in the isospin $I=0$ and $I=2$ states was determined [19], where the main source of uncertainty was due to the ratio of the branching ratios $K^+ \to \pi^+ \pi^- \pi^0$ and $K^+ \to \pi^+ \pi^0 \pi^0$.

New measurement performed at KLOE [20] is based on the two samples selected with the usage of $K^+ \to \mu^+ \nu(\gamma)$ ($K_{\mu2}$ tags) and $K^+ \to \pi^+ \pi^0(\gamma)$ ($K_{\pi2}$ tags) events. These independent samples of pure kaons for the signal selection are useful for systematic uncertainties evaluation and cross-checks [21]. The above mentioned decays are identified from the momentum of the charged secondary track in the kaon rest frame evaluated using the pion mass hypothesis, the selection efficiency of the two tagging normalization samples are similar and about 36%. In order to reduce influence of the trigger efficiency on the signal side a normalization sample of $K_{\mu2}$ or $K_{\pi2}$ tags is selected. In addition $K^-$ is used as the tagging kaon ($K_{\mu2}$ or $K_{\pi2}$) and $K^+$ as the tagged kaon (signal) due to factor of $\sim 10^3$ lower the nuclear cross section for positive kaons with momenta $\sim 100$ MeV with respect to that of negative kaons [22].

To evaluate the momentum of the tagged kaon at the interaction point (IP) the momentum of the tagging kaon at the IP (backward extrapolated from its first hit in the drift chamber (DC)) and momentum of the $\phi$-meson measured run by run with Bhabha scattering events are used. Then momentum of $K^+$ is extrapolated inside the DC (path of the signal kaon). Requirement of the position of $K^+$ decay vertex inside inner radius of the drift chamber is applied in order to decrease number of charged track in the DC, since both kaon and pions have momenta lower than $\sim 200$ MeV and therefore curl up in the KLOE magnetic field, which increases number of tracks reconstructed with low quality. Additionally only two of the pion tracks are reconstructed to search for a vertex along the signal kaon path.

The number of $K^+ \to \pi^+ \pi^- \pi^0(\gamma)$ is extracted from
the comparison of the MC-predicted shapes for the signal and the background and the experimental missing mass spectrum $m_{miss}^2 = E_{miss}^2 - (p_K - p_1 - p_2)^2$ where $p_1$ and $p_2$ are the momenta of the selected tracks.

The branching ratio is given by:

$$BR(K^+ \rightarrow \pi^+\pi^-\pi^0(\gamma)) = \frac{N_{K^+\rightarrow 3\pi}}{N_{tag}} \times \frac{1}{\epsilon} \quad (4)$$

where $N_{K^+\rightarrow 3\pi}$ is the number of signal events, $N_{tag}$ is the number of tagged events and $\epsilon$ is the overall signal selection efficiency (detector acceptance, reconstruction efficiency, tag bias, corrections for the machine and cosmic-ray background).

The effect of the influence of the charged kaon lifetime through the detector acceptance on the BR($K^+ \rightarrow \pi^+\pi^-\pi^0(\gamma)$) was also evaluated based on the MC simulation and then applied as weight to the MC events, both for the signal and the control sample selection procedures.

Averaging two results for $K^- \rightarrow \mu^-\nu(\gamma)$ and $K^- \rightarrow \pi^-\pi^0(\gamma)$ samples, accounting for correlations, the final result of the measurement is [20]:

$$BR(K^- \rightarrow \pi^-\pi^+\pi^0(\gamma)) = 0.05565 \pm 0.00031_{stat} \pm 0.00025_{syst}, \quad (5)$$

which is fully inclusive of final-state radiation and has a 0.72% accuracy, which makes it a factor ≈ 5 better with respect to the previous measurement [10].

5. KLOE–2 project

The KLOE detection system is now upgraded with the Inner Tracker detector [23], which will improve resolution on the vertex position and acceptance for tracks with low transverse momentum; with two pairs of small angle tagging devices to detect low (Low Energy Tagger - LET [24]) and high (High Energy Tagger - HET [25]) energy $e^+e^-$ originated from $e^+e^- \rightarrow e^+e^-X$ reactions; new crystal calorimeters (CCALT) to cover the low polar angle region to increase acceptance for very forward electrons and photons down to 8° [26]; and a tile calorimeter (QCALT) used for the detection of photons coming from $K_L$ decays in the drift chamber [27].

These upgrades will improve systematic uncertainties for KLOE–2 measurements [28], while statistical uncertainties will be improved due to higher luminosity of the DAΦNE collider.

6. Conclusions

Recent results of KLOE explore fundamental symmetries with $10^{-18}$GeV sensitivity on Standard Model Extension parameters with application of kaon interferometry, and completes the KLOE program of precision measurements of the dominant kaon branching ratios. The new KLOE–2 setup started operations at an upgraded DAΦNE collider for an extension of the original KLOE physics program.
