Predictors of first nonfatal occupational injury following employment in a Brazilian steelworks

by Sandhi M Barreto, PhD,1 Anthony J Swerdlow, PhD,2 Minouk J Schoemaker, MSc,2 Peter G Smith, PhD3

Objectives This study investigated the influence of sociodemographic and occupational factors on the risk of 1st injury among Brazilian steelworkers.

Methods Workers 1st employed between 1 January 1977 and 31 December 1985 and still employed on 1 December 1983 were followed from the date of hire until 30 October 1992. Occupational injuries were ascertained from a database. Kaplan-Meier curves for time to 1st injury were calculated for the total cohort and for different subgroups. A multivariate analysis of risk factors for 1st injury was carried out using the Cox proportional hazards regression model.

Results Forty-one percent of the workers had ≥1 occupational injuries, and 39% of 1st injuries occurred in the 1st year of employment. Lacerations, contusions, penetration by foreign bodies, burns, sprains, and fractures constituted the main diagnostic groups. Injuries to the hands, eyes, feet, arms, and legs dominated. Over 5% of the injured workers were on temporary disability leave (cumulative total 10 660 days). The probability for an occupational injury was 16% for the 1st year, rising to 25% in the 2nd year. The risk of nonfatal injury was highest for laborers [hazard ratio (HR) 1.76, 95% confidence interval (95% CI) 1.35—2.29] and employees in the steel mill (HR 1.40, 95% CI 1.21—1.63), and inversely related to worker age and educational level. The risk of injury decreased significantly with calendar period of employment.

Conclusions Substantial reductions in nonfatal injuries may reflect changes in work organization, increased automation, and improved safety standards. Knowledge of predictors of work-related injury may contribute to injury prevention strategies, especially among newly employed workers.

Key terms cohort study, education, steel workers, work-related injury.

The workplace is a significant contributor to fatal and nonfatal injuries worldwide and an insufficiently appreciated contributor to the total burden of health care costs. In the United States, for instance, estimates of the number of nonfatal work-related injuries range from 6 to 13 million annually (1—3), and the total annual cost of work-related injuries and fatalities has been estimated to be greater than USD 121 billion (4).

In Brazil, occupational injury rates are 2 to 4 times higher than in most industrialized countries (5). In 1996, work-related injuries accounted for 91.2% of all reported workplace morbidity among the employed urban population, totaling 361 755 cases. In the same year, the National Institute of Social Security spent around USD 5 million on rehabilitation programs for injured workers. Altogether 428 072 employees were treated for occupational injury. Of this number 45.2% had work absences of up to 15 days, 37.3% had long-term disabilities (loss of more than 15 workdays), 5.9% had permanent disability, and 1.3% of the injuries were fatal.

As in many other countries, however, occupational injuries are underreported in Brazil (5, 6). The main reason for the underreporting is that the national database (from which the data on occupational injuries derive) excludes public-sector employees and rural, self-employed, and informal or temporary workers.

The risk of injury-related disability seems to increase with the number of injuries a worker has had previously (7, 8). Work experience seems also relevant to injury prevention, since injury risk is inversely related to duration of employment (9, 10). Identifying personal and occupational predictors of work-related injury may contribute to injury-prevention strategies, especially among newly employed workers. We have tried to assess the influence of social and demographic factors on the risk of 1st injury in the workplace, after taking into account the effect of other relevant factors, such as year of starting employment, place of work, and job category.

Subjects and methods

The study was carried out using data from a very large steelworks in southeast Brazil, the 2nd largest steel producer in the country with a work force of about 12 500. A large cohort study had previously been undertaken to investigate the mortality of workers at the plant (11—13). This cohort comprised 21 816 men employed at the plant at any time between 1 January 1977 and 31 August 1992. Details of the methods used to assemble the cohort and to follow the members have been published elsewhere. (11) In the present study, data from a subset of the cohort were analyzed because sociodemographic information could only be collected for this group. The subset consisted of 6609 workers who began work in the plant between 1 January 1977 and 31 December 1985 and who were still employed in the plant on 1 January 1983 if they had started work in the plant before that date.

We confined the analysis to nonfatal occupational injuries that occurred during the workshift and that resulted directly from a worker’s job or to which the worker’s job was a contributory factor. The injuries were ascertained using the database of the Occupational Hygiene Department, which contained information for all workers on the date and site of injury, type of tissue damage, number of workdays lost as a result of any reported injury, any sequelae, and other general information about the worker. Information about the injury had been recorded by the plant hygienists on the day of its occurrence. This database was considered to be virtually complete and was used to produce the official report on the occurrence of injuries for the Ministry of Labour.

The cohort members were classified according to their age at the start of employment (≤ 18, 19—25, ≥ 26 years), period of start of employment (1977—1979, 1980—1982, 1983—1985), educational level (≤ 4, 5—8, 9—11, ≥ 12 years of school attendance), and marital status at the time of admission to the plant (single, married, other). Information on job category (professionals and technicians, clerks, and laborers) and place of work at the beginning of work in the steelworks was also used in the analysis. To summarize the data for the statistical analysis, we grouped the place of work into the following 7 major areas based on production flow: administration, research, quality and production control; maintenance; energy supply; cranes and other heavy motor vehicles; cold and hot strip mills; steel mill; and coke and foundry areas.

Workers were followed from the date they started work at the plant to the time they left the plant, their death, or 30 October 1992, whichever was earliest. Kaplan-Meier curves for time to 1st injury were calculated for the total cohort and for subgroups by age, period of 1st employment, school level, marital status at entry to work, occupational group, and place of work. The curves were tested for heterogeneity using the log-rank test. A multivariate analysis was carried out using the Cox proportional hazards regression model to assess the effect of the different factors on time to 1st occupational injury. The assumption of proportional hazards was checked by plotting the logarithm of the cumulative baseline rate against the logarithm of time since 1st employment by the explanatory variable and assessing whether the lines were parallel (14). The analysis was conducted using Stata statistical software (15).

Results

As the cohort consisted of workers who had entered the industry between 1977 and 1985, the period of follow-up varied from 7 to 16 years. Data were missing for 116 (1.7%) workers, and hence 6493 men were included in the analyses. A total of 2686 workers had at least 1 injury at the worksite, and 1104 had ≥ 2 injuries. Table 1 shows the distribution of the workers according to the number of occupational injuries recorded.

Among the 2686 workers with ≥ 1 occupational injuries, the 1st occupational injury led to loss of workdays for 143 workers and resulted in permanent disability for 8 of these workers. Altogether 10 660 (median 29) days of work were lost as a result of 1st injuries, and the industry paid the equivalent of 9260 days in compensation for permanent disability. The remaining 2543 first-time injured workers were able to return to work on the following workday.

Lacerations, cuts, and scrapes accounted for 36% of the 1st injuries followed by contusions and hematomas, foreign bodies and burns, chemical burns, and scalds (table 2). Hands were the anatomic sites sustaining the most first-time injuries, followed by eyes, feet, arms, and legs (table 3).

The results of the Kaplan-Meier analyses of time to 1st accident are given in figure 1, which shows the pro-
portion of workers remaining injury-free at different times since 1st employment. Sixteen percent (N=1055) of the cohort had an occupational injury during their 1st year of employment, the proportion remaining injury-free being 84% [95% confidence interval (95% CI) 83—85%]. At the end of the 2nd year of employment the percentage of those who had not had any injury decreased to 75% (95% CI 74—77%), after 7 years it was 60% (95% CI 64—66%), and after 15 years it was 53% (95% CI 51—55%) (figure 1a).

The risk of injury reduced substantially with calendar period of employment (figure 1b). The percentage of workers who were injury-free after 1 year of employment was 79% (95% CI 78—81%) for workers who started work during 1977—1979, 89% (95% CI 87—90%) for workers employed in 1980—1982, and 93% (95% CI 91—94%) for those employed in the latest period (1983—1985). The 7-year cumulative accident-free rates related to the same periods of employment were 57% (95% CI 55—58%), 67% (95% CI 64—70%), and 73% (95% CI 70—76%), respectively. The curves for the 3 periods were significantly different (χ² 2 df: 130, P<0.001).

Younger workers were more likely to have an injury than older workers (figure 1c). The difference in the injury-free rates between the youngest and the oldest age groups at the time of employment appeared to widen over time, being, at the end of the follow-up, 45% for the workers 1st employed before 19 years of age and 56% for the workers employed at later ages.

There was a marked and statistically significant difference in the accident-free curves (χ² 3 df: 389, P<0.001) according to educational level (£4, 5—8, 9—11, ≥12 years of school) (figure 1d). After 1 year of employment the probability of having had no injury for each educational group was 76%, 82%, 92% and 98%, respectively, declining to 41%, 50%, 73%, and 88% after 15 years. In relation to marital status, married workers had the better injury-free curve (figure 1e), followed by single workers and other marital statuses, respectively (χ² 2 df: 19.5, P<0.001).

Information on job category at the start of employment was available for 6407 workers in the cohort and missing for 86. Sixty-three percent were laborers, 23% were clerical workers, and 12% were professional or technical workers. Job category was an important prognostic factor for being free of injury (χ² 2 df: 245, P<0.001). Laborers had the worst injury records with a probability of 80% for having no injury in the 1st year (95% CI 79—81%), compared with 87% (95% CI 85—89%) and 95% (95% CI 94—97%) for clerical and professional workers, respectively (figure 1f).

Data on area of work within the plant at the start of employment were missing for 253 cohort members. For-}

| Total                   | 2686            | 100     |
The multivariate Cox regression analysis showed that age and calendar period of start of employment, school level, 1st job category, and place of work were independent risk factors for nonfatal injury, but marital status was not related to risk after adjustment for the other factors ($\chi^2$ 2 df: 0.67, $P=0.72$). In the final model (table 4), workers 1st employed at the age of $\geq 19$ years had a more than 40% lower risk of occupational injury than those 1st employed at younger ages. The risk decreased significantly and substantially between the workers starting employment in 1977—1979 and 1983—1985 ($P<0.001$). There was a highly significant inverse association between educational level and risk of injury ($P<0.001$). After adjustment for other factors, laborers remained significantly more likely than professional and technical workers to have an occupational injury [hazard ratio (HR) 1.76, 95% CI 1.35—2.29]. The risk of injury varied only slightly between different areas of work,
although there was a significantly increased risk for employees working in the steel mill area (HR 1.40, 95% CI 1.21—1.63) and a significantly reduced risk for employees in energy supply (HR 0.79, 95% CI 0.63—0.97) and the crane and other motor vehicles category (HR 0.75, 95% CI 0.60—0.94) than for those working in administration and production control.

**Discussion**

The probability of suffering an occupational injury in the 1st year of employment was 16%, increasing to 25% by the end of the 2nd year. We identified the following 5 independent predictors of 1st nonfatal injury following employment in the steel plant: age and period of starting employment, school level, 1st job category, and work area.

The hazard ratios were inversely related to age and period at the start of employment. The highest risk was found for men aged ≤18 years at the time of employment. Several studies have found an increased risk of occupational injury among younger workers (1, 2, 16, 17). A previous analysis of our cohort found that rates for fatal occupational injury were greatest among workers aged <25 years and >45 years and that mortality was highest in the 1st year of employment (10). In the United States, workers aged 16 and 17 years were at greater risk of death from occupational injury than older workers were (18). It is very difficult to separate out the effect of youth and inexperience as age is highly correlated with work experience. Younger and inexperienced workers might also be less able to respond to new hazards as they arise or might adopt risky behavior.

The substantial reduction in the risk of nonfatal injury for workers employed in later periods may be explained by increased automation and changes in the work organization. It may also reflect some improvement in safety strategies with time. There was a similar decrease in the rates of work-related injury in the country overall in the same period (5). Although records for this cohort were considered virtually complete, it is not possible to rule out some minor underreporting. It has been argued that safety incentives may have an indirect, but significant negative influence on the reporting of workplace injuries (19). The safety incentive program adopted in the steelworks during the study period was based on rewards for safety-related changes (barbecues, prizes, etc), and it therefore may have encouraged some underreporting. Nevertheless, any plausible change in the reporting rates in the period would not explain the sharp and steady declining trend in injury rates that we found for this cohort.

The increase in time to 1st injury with increased schooling may be partially explained by residual confounding with job category, since adjustment was based on a crude categorization of jobs, and job title is highly correlated with level of education. We have previously found that lack of schooling was associated also with fatal work-related injuries (12). It is possible that education itself also plays a role in reducing injury risk, by increasing the awareness of risk among those who are better educated or promoting cautious attitudes towards hazards.

The finding of a significant increased risk of injury among the laborers, even after adjustment for education, is likely to reflect greater exposure to hazards in the workplace. The mortality rates for occupational injury were also greater for laborers in the same period (11). There are many unsafe areas in the steel plant, and the steel mill was the one associated with the greatest risk of injury. It is possible that less-skilled workers were more often employed in this area than in other producing areas. This area is the largest in the plant and areas that need less-skilled workers are concentrated there, for example, coal stock and primary ore and blending yards. The reverse, employment of more-skilled workers, may explain the lower risk observed for workers 1st employed in the administration and support, energy supply, cranes and motor vehicles, coke production, and plate mill areas.

Using lost workdays to assess the severity of occupational injury may have seriously underestimated the

| Risk factor | Hazard ratioa | 95% CI |

| Steel mill | 1.40 | 1.21—1.63 |

*a* After adjustment for all other factors in the table.
Predictors of 1st nonfatal injury after employment

magnitude of the problem in this study, since most workers with fractures, amputations of fingers, and other potentially serious injuries were temporarily assigned to other tasks or areas while recovering from their injury. This policy was aimed at reducing injury costs, and it also had a favorable impact on the apparent effectiveness of the injury prevention program adopted. An important goal of the ongoing program at that time was to reduce the number of lost-time injuries.

Although fractures accounted for only 4.8% of the 1st injuries (table 2), they often impair a worker’s skill. In this study most of the fractures affected hands, arms, or legs. Nonlife threatening injuries, such as injuries to the hand and arms, resulting from accidents in the workplace reduce the number of lost-time injuries.

The populations at higher risk for various types and levels of severity of injuries is an important prerequisite for developing effective injury prevention programs. However, we have already addressed the issue of recurrent injury using the Cox regression. An alternative method behind this analysis, in which we investigated factors that affected the time to 1st injury in a subset of newly employed workers for whom we could extract additional information on potential explanatory factors.

Unfortunately, the database available for our study had no information on the immediate antecedents of injuries. Such information is necessary for a more-detailed investigation of injury risks and would aid the design of strategies for injury prevention. However, knowledge of the populations at higher risk for various types and levels of severity of injuries is an important prerequisite for developing effective injury prevention programs.
