Abstract

Using accurate multi-component diffusion treatment in numerical combustion studies remains formidable due to the computational cost associated with solving for diffusion velocities. To obtain the diffusion velocities, for low density gases, one needs to solve the Stefan-Maxwell equations along with the zero diffusion flux criteria, which scales as $O(N^3)$, when solved exactly. In this article, we propose an accurate, fast, direct and robust algorithm to compute multi-component diffusion velocities. We also take into account the Soret effect, while computing the multi-component diffusion velocities. To our knowledge, this is the first provably accurate algorithm (the solution can be obtained up to an arbitrary degree of precision) scaling at a computational complexity of $O(N)$ in finite precision. The key idea involves leveraging the fact that the matrix of the reciprocal of the binary diffusivities, $V$, is low rank, with its rank being independent of the number of species involved. The low rank representation of matrix $V$ is computed in a fast manner at a computational complexity of $O(N)$ and the Sherman-Morrison-Woodbury formula is used to solve for the diffusion velocities at a computational complexity of $O(N)$. Rigorous proofs and numerical benchmarks illustrate the low rank property of the matrix $V$ and scaling of the algorithm.

1. Introduction

Computational combustion studies typically employ an approximate mixture-averaged diffusion treatment with velocity correction [1]. However, several works have pointed to the need for accurate treatment of multi-component species diffusion in the presence of high concentration gradients and in simulations that capture the structure of flames [2–9]. For instance, Bongers and De Goey [4] found that errors up to 10% occur in the burning velocities of methane/oxygen and hydrogen/oxygen flames with an approximate diffusion treatment. Gopalakrishnan and Abraham [5] investigated the ignition of \( n \)-heptane/air diffusion flames, and reported a 10% difference in the transient temperature and major species profiles when using an approximate diffusion model. In a numerical study with different transport models, Dworkin et al. [8] found deviations up to 15% in peak soot volume fraction in ethylene/air coflow flames, although only small differences were observed in temperature profiles. In the case of combustion of \( n \)-heptane droplet in a forced-convection environment, Pope and Gogov [7] found that extinction velocity, maximum temperature, flame dimensions, evaporation constant, and drag coefficient are significantly different between using single binary diffusion coefficient and multi-component diffusion coefficients. Xin et al. [9] found marked deviations for peak temperatures between mixture-averaged and multi-component diffusion treatments at elevated pressure and large strain rates in counterflow diffusion flames and in droplet ignition. Even for turbulent configurations, Hilbert et al. [6] found the choice of transport model to play an essential role, in particular for high flame curvatures and far from stoichiometry. However, using accurate multi-component diffusion treatment in numerical combustion studies remains formidable due to the computational cost associated with solving for diffusion velocities.

For low density gases, the diffusion velocities are obtained by solving the Stefan-Maxwell equations [10–12]:

\[
\nabla X_p = \sum_{k=1}^{N} \frac{X_p X_k}{D_{pk}} (v_k - v_p) + \sum_{k=1}^{N} \frac{X_p X_k}{D_{pk}} \left( \frac{D_k^{(T)}}{Y_k} - \frac{D_p^{(T)}}{Y_p} \right) \frac{\nabla T}{\rho T} + \frac{\rho}{P} \sum_{k=1}^{N} Y_p Y_k (f_p - f_k) \tag{1}
\]

\[

\nabla X_p = \sum_{k=1}^{N} \frac{X_p X_k}{D_{pk}} \left( v_k + \frac{\nabla T}{\rho T} \frac{D_k^{(T)}}{Y_k} \right) - \left( v_p + \frac{\nabla T}{\rho T} \frac{D_p^{(T)}}{Y_p} \right) + \frac{\rho}{P} \sum_{k=1}^{N} Y_p Y_k (f_p - f_k) \tag{2}
\]

where \( N \) is the number of species, \( X_k \)'s are the mole fractions, \( v_k \)'s are the diffusion velocities, \( D_{pk} \)'s are binary diffusion coefficients, \( D_k^{(T)} \)'s are the thermal diffusion coefficients, \( T, \rho \) \& \( P \) are the temperature, density \& pressure of the mixture, and \( f_k \)'s denote the body forces. Equation (1) can be rewritten as shown in Equation (2).
From kinetic theory (assuming elastic collisions), $D_{pk}$ is given by

$$D_{pk}^E = K_1 \left( \frac{k_B T}{\pi} \right)^{3/2} \frac{1}{P} \frac{1}{\sqrt{m_{pk}(d_p + d_k)^2}},$$  \hspace{1cm} (3)$$

where $P$ is the pressure, $T$ is the temperature, $k_B$ is the Boltzmann's constant, $m_{pk}$ is the reduced mass of species $p$ & $k$ and $d_p$, $d_k$ are the collision diameter for species $p$ & $k$ respectively. To take inelastic collisions into account, Equation (3) must be modified by a collision integral $\Omega_{pk}$ as,

$$D_{pk}^I = K_2 \left( \frac{k_B T}{\pi} \right)^{3/2} \frac{1}{P} \frac{1}{\sqrt{m_{pk}(d_p + d_k)^2}\Omega_{pk}},$$  \hspace{1cm} (4)$$

where $\Omega_{pk} = \Omega_{pk} \left( \frac{k_B T}{\epsilon_{pk}} \right) = \Omega_{pk} (T^*)$ and $K_1, K_2$ are two fixed constants.

Note that although there are $N$ equations in Equation (2), only $N-1$ of these are independent. Therefore, the diffusion velocities $v_k$’s are solved for in Equation (2) along with the flux criterion that

$$\sum_{k=1}^{N} Y_k v_k = 0 \implies \sum_{k=1}^{N} W_k (X_k v_k) = 0$$  \hspace{1cm} (5)$$

where $Y_k$ is the mass fraction, $X_k$ is the mole fraction and $W_k$ is the molecular mass of species $k$. Solving the linear system using Equations (2) and (5) to obtain the diffusion velocities requires $O(N^3)$ operations. In unsteady multi-dimensional problems with detailed chemistry, a computational cost of $O(N^3)$ at every grid point in the domain and at every time step must be expended, making the computation time consuming and therefore out of practical reach.

Ern and Giovangigli proposed iterative methods [13–15] to obtain approximate solutions to the above equations, where all transport coefficients are expressed as convergent series and are approximated by the truncation of these series, as implemented in the EGLIB software package [16]. Each iteration involves matrix vector products, which need $O(N^2)$ operations. If $n_i$ iterations were involved in their method, the total computational cost to obtain $v_k$’s will be $O(n_i N^2)$. Recently, Xin et al. [9] proposed a reduced multi-component model, using a multi-component diffusion treatment for critical-diffusivity-species (identified using sensitivity analysis) and mixture averaged diffusion treatment for the others. The computational complexity of their model scales linearly with the size of the number of species. A correction velocity must be applied to their diffusion velocities to ensure net species diffusion flux is zero, since their model is a hybrid of the multi-component model and the mixture-averaged model.

In the earlier studies that focused on obtaining solutions to the Stefan-Maxwell equations in faster computational time, the nature of the matrices underlying these equations have not been given attention. This will be the focus of the present work. We propose an accurate, fast, mathematically provable and robust, universal,
direct (non-iterative) algorithm to solve for multi-component diffusion velocities by leveraging the inherent low rank structure of the matrix formed by the reciprocal of the binary diffusion coefficients. This direct algorithm to compute diffusion velocities involves $O(N)$ operations in finite precision. An important feature of this algorithm is that the accuracy of the low-rank factorization is a user input, which in turn can be used \textit{apriori} to quantify the accuracy of the solution (in this case the diffusion velocities), unlike the methods proposed earlier \cite{9, 13, 15}. In addition, no velocity correction is needed in this approach, since the flux criterion (Equation 5) is also satisfied. Further, there is no costly pre-computation step, such as sensitivity analysis, involved in this algorithm. In fact, the total time taken by our algorithm to obtain diffusion velocities is orders of magnitude faster than the conventional LU factorization based algorithm even for a small number of species ($\sim 200$).

This article is organized as follows. In Section 2 the low rank structure of the matrix whose entries are the reciprocal of binary diffusivities is rigorously analysed. Following this, in Section 3 the key ingredients of the algorithm and the pseudo-code are presented. The computational complexity of the algorithm is demonstrated in Section 4 followed by accuracy analysis and comparison to exact solution. Section 5 concludes the article by highlighting the main contributions and applicability of the algorithm.

2. Structure of the binary diffusion matrix

Letting $z_k = X_k \cdot \left( v_k + \frac{\nabla T D_k^{(T)}}{\rho T Y_k} \right)$, the Stefan-Maxwell equation (Equation 2 in Section 1) can be rewritten as

$$\sum_{k=1}^{N} \frac{X_p z_k}{D_{pk}} - \sum_{l=1}^{N} \frac{X_l z_p}{D_{pl}} = \nabla X_p - \left(Y_p - X_p\right) \frac{\nabla P}{P} - \frac{\rho}{P} \sum_{k=1}^{N} Y_p Y_k \left(f_p - f_k\right)$$

which when written in a matrix form gives us Equation 7.

$$Az = b$$

where $A \in \mathbb{R}^{N \times N}$ and $z, b \in \mathbb{R}^{N \times 1}$. The entries of $A$ and $b$ are as given in Equations 8 and 9.

$$A_{pk} = \delta_{pk} \sum_{l=1}^{N} \frac{X_l}{D_{pl}} - \frac{X_p}{D_{pk}}$$

$$b_p = -\nabla X_p + \left(Y_p - X_p\right) \frac{\nabla P}{P} + \frac{\rho}{P} \sum_{k=1}^{N} Y_p Y_k \left(f_p - \tilde{f}\right)$$

where $\tilde{f} = \sum_{l=1}^{N} Y_l f_l$. Note that the entire vector $b$ (i.e., the right hand side of the linear system in Equation 7) can be computed at cost of $O(N)$. 

Letting $V$ to denote the matrix containing the reciprocal of the binary diffusion coefficients, i.e., $V_{pk} = \frac{1}{D_{pk}}$, we see that

$$A = \text{diag}(VX) - \text{diag}(X)V$$

(10)

The key structure that we will exploit is that the matrix $V$ is a low-rank matrix. In fact, in the next subsection, we prove that this is indeed the case, when the molecules undergo elastic collisions. We also present numerical benchmarks, which give additional evidence to the fact that the matrix $V$ is low-rank for both elastic and inelastic collisions.

2.1. Elastic collisions

When the molecules undergo elastic collisions, since we have a simple expression for $V_{ij}$, we will show using analytic means that the matrix $V$ is truly low-rank, i.e., the rank of the matrix $V$ up to machine precision doesn’t scale with the size of matrix (the rank is independent of $N$).

From Equation (3), writing the reciprocal of the binary diffusion coefficient, we have the elements of the matrix $V \in \mathbb{R}^{N \times N}$ given by

$$V_{ij} = K \frac{P}{T^{3/2}} (d_i + d_j)^2 \sqrt{m_i m_j}$$

where $K$ is a constant. If we can represent $1/\sqrt{m_i + m_j}$ in a separable form as $\sum_{k=1}^{p} f_k(m_i) s_k f_k(m_j)$, we then have

$$V_{ij} = K \frac{P}{T^{3/2}} (d_i + d_j)^2 \sqrt{m_i m_j} \left( \sum_{k=1}^{p} f_k(m_i) s_k f_k(m_j) \right)$$

(11)

$$= K \frac{P}{T^{3/2}} \left( \sum_{k=1}^{p} (d_i^2 \sqrt{m_i} f_k(m_i)) s_k (\sqrt{m_j} f_k(m_j)) + (d_i \sqrt{m_i} f_k(m_i)) (2s_k) (d_j \sqrt{m_j} f_k(m_j)) + (\sqrt{m_i} f_k(m_i)) s_k (d_j^2 \sqrt{m_j} f_k(m_j)) \right)$$

(12)

$$= K \frac{P}{T^{3/2}} \left( \sum_{k=1}^{p} (d_i^2 \bar{U}_{ik}) s_k \bar{U}_{jk} + \sum_{k=1}^{p} (d_i \bar{U}_{ik}) (2s_k) (d_j \bar{U}_{jk}) + \sum_{k=1}^{p} \bar{U}_{jk} s_k (d_j^2 \bar{U}_{jk}) \right)$$

(13)

where $\bar{U}_{jk} = \sqrt{m_j} f_k(m_j)$. Writing this in matrix form, we obtain that

$$V = K \frac{P}{T^{3/2}} \left((D^2 \bar{U})S\bar{U}^T + (\sqrt{2}D\bar{U})(S)(\sqrt{2}D\bar{U})^T + \bar{U}D(SD^2\bar{U})^T\right)$$

(14)

$$= K \frac{P}{T^{3/2}} \left[D^2\bar{U} \quad \sqrt{2}D\bar{U} \quad \bar{U} \right]_{N \times (3p)} \left[ S \ 0 \ 0 \\ 0 \ S \ 0 \\ 0 \ 0 \ S \right]_{(3p) \times (3p)} \left[D^2\bar{U} \right]_{(3p) \times N}$$

(15)

where $D = \text{diag}(d) \in \mathbb{R}^{N \times N}$ and $S = \text{diag}(s) \in \mathbb{R}^{p \times p}$, which means the rank of $V$ is at-most $3p$. We will
now prove that \( \frac{1}{\sqrt{m_i + m_j}} \) can be efficiently represented in a separable form. There are many ways to obtain a separable form for \( \frac{1}{\sqrt{m_i + m_j}} \). One way is to use a Taylor series representation making use of the fact that 
\[ 1 \leq m_i, m_j \leq M. \] However for a compact argument, we choose to make use of the identity

\[
\frac{1}{\sqrt{m_i + m_j}} = \frac{2}{\sqrt{\pi}} \int_0^\infty \exp(-(m_i + m_j)y^2)dy
\]

Recall that \( 2 \leq m_i + m_j \leq 2M \). Hence, all we need is an efficient quadrature of \( \int_0^\infty e^{-xy^2}dy \) for \( x \in [2, 2M] \).

Recall that the tail of the integral has the following bounds, i.e., we have

\[
\int_t^\infty e^{-xy^2}dy < e^{-xt^2}/2tx
\]

Hence, for \( x \in [2, 2M] \), we have that

\[
\int_t^\infty e^{-xy^2}dy \leq \int_t^\infty e^{-2y^2}dy < e^{-2t^2}/4t
\]

In fact, for \( t = 4 \), we hit an error bound close to machine precision for \( x \geq 2 \), i.e.,

\[
\int_4^\infty e^{-xy^2}dy < 10^{-15}
\]

We hence have

\[
\frac{1}{\sqrt{m_i + m_j}} = \epsilon_m \frac{2}{\sqrt{\pi}} \int_0^4 e^{-(m_i + m_j)y^2}dy
\]

where \( \epsilon_m = 10^{-15} \) and \( a = \epsilon_m b \) is to be interpreted as \(|a - b| < \epsilon_m \). There exists a wide range of quadratures we can deploy to obtain arbitrary accuracy we want, i.e.,

\[
\frac{1}{\sqrt{m_i + m_j}} = \epsilon_m \sum_{k=1}^p w_k e^{-(m_i + m_j)y_k^2} = \sum_{k=1}^p e^{-m_i y_k^2} w_k e^{-m_j y_k^2} = \sum_{k=1}^p f_k(m_i) s_k f_k(m_j)
\]

Hence, if we form the matrix \( L \in \mathbb{R}^{N \times N} \), where \( L_{ij} = \frac{1}{\sqrt{m_i + m_j}} \), we then have that \( L = HCH^T \), where \( H \in \mathbb{R}^{N \times p} \) with \( H_{ik} = e^{-m_i y_k^2} \) and \( C \in \mathbb{R}^{p \times p} \) is a diagonal matrix.

The low-rank decomposition of the matrix \( V \) obtained above by analytic means provides a sub-optimal upper bound on the rank. The Singular Value Decomposition (SVD) of the matrix \( V \) gives us the optimal rank, though obtaining the SVD is computationally expensive (scaling as \( \mathcal{O}(N^3) \)). We will see in Section 3.1 that the rank and low-rank decomposition of the matrix \( V \) can be obtained by purely algebraic means in a fast way, i.e., at a computational cost of \( \mathcal{O}(N) \). We see from Figure 1(a) that the rank of the matrix \( L \) (up to machine precision) is an extremely weak function of the maximum mass \( M \). More importantly, the analytic argument proves that the
rank of the matrix \( L \) (up to machine precision) is independent of the number of species \( N \) and in fact the rank \( \ll N \) as shown in Figure 1(b). Note that the rank of the matrix \( L \) (up to machine precision) doesn’t exceed 25, even though the number of species is a few thousands.

(a) Maximum mass is varied keeping the number of species as 5000.

(b) Number of species is varied keeping the max mass as 200.

Figure 1: Decay of singular values of the matrix \( L \) (normalized with the largest singular value). The masses of the \( N \) species are uniformly distributed from 1 to the maximum mass in all cases.

2.2. Inelastic collisions

For inelastic collisions, the binary diffusion coefficient is given by Equation (4). Using numerical benchmarks, we illustrate the low rank property of the matrix \( V \) arising out of the species involved in a comprehensive chemical mechanism proposed by Sarathy et al. [17] for a wide range of methyl alkanes. From the total of 7171 species involved in this kinetic scheme, we obtained a sequence of subsets of species (retaining the species with maximum and minimum masses) of different sizes \( N \in \{226, 450, 898, 1794, 3586, 7171\} \). For each of these subsets, we form the matrix \( V \) and analyze its \( \epsilon \)-rank as a function of the number of species \( N \). The \( \epsilon \)-rank of a matrix is the number of singular values, which are within a factor of \( \epsilon \) of the largest singular value, i.e., if a matrix \( A \in \mathbb{R}^{N \times N} \) with singular values \( \sigma_1, \sigma_2, \ldots, \sigma_N \), has an \( \epsilon \)-rank of \( r \), this means that \( \frac{\sigma_k}{\sigma_1} < \epsilon \) iff \( k > r \). Figures 2(a) and 2(b) show that the \( \epsilon \)-rank of the matrix \( V \) is independent of the number of species for elastic and inelastic collisions respectively. Further, even if we set \( \epsilon = 10^{-14} \), which is very close to the machine precision, we see that the rank of the matrix \( V \) is still orders of magnitude smaller than \( N \). Also, not surprisingly, if lesser accuracy is sought for, then the \( \epsilon \)-rank decreases further.
Figure 2: The maximum of the \( \epsilon \)-rank over all the grid points as a function of number of species in the subset of species involved in Sarathy et al. \[17\] mechanism. It is evident that the \( \epsilon \)-rank is independent of \( N \) and decreases with decrease in accuracy.

3. Methodology

In the previous section, we illustrated that the matrix \( V \) has an inherent low-rank structure. In order to leverage this structure for computing diffusion velocities in a fast manner, we need to perform two significant steps:

1. Obtain low-rank factorization of the matrix \( V \)
2. Use this low-rank factorization to obtain diffusion velocities

In order for our algorithm to scale as \( O(N) \), both these steps must scale as \( O(N) \).

3.1. Fast low-rank factorization

If the matrix \( V \in \mathbb{R}^{N \times N} \) has an \( \epsilon \)-rank \( r \), we factorize \( V \) as \( LR^T \), where \( L, R \in \mathbb{R}^{N \times r} \) such that

\[
\|V - LR^T\|_2 \leq \epsilon
\]

The optimal \( \epsilon \)-rank is given by the SVD \[13\], though SVD is computationally expensive, scaling as \( O(N^3) \), which defeats our purpose. Thankfully in recent years, there has been an increasing focus on constructing fast \( (O(N)) \), accurate, low-rank factorizations \[19, 22\] for matrices. Some fast techniques such as multipole expansions, analytic interpolation, Adaptive Cross Approximation (ACA) \[23, 24\], pseudo-skeletal approximations \[25\], interpolatory decomposition, randomized algorithms \[26\], rank-revealing LU and QR algorithms provide a great way for constructing efficient low-rank representations.

In this article, we rely on the Partially Pivoted Adaptive Cross Approximation \[23\] (PPACA) algorithm, which scales as \( O(r^2N) \) to construct a low-rank factorization of matrix \( V \), where \( r \ll N \) is the rank obtained.
using PPACA. The PPACA proceeds by obtaining an input accuracy $\epsilon_{\text{inp}}$ from the user and subsamples the rows and columns of the matrix (similar to the partially pivoted LU algorithm) to construct a low-rank factorization of the matrix up to the desired input accuracy $\epsilon_{\text{inp}}$. In the past, PPACA has been used to compress a wide range of matrices including those arising out of $N$-body problems \[27\], integral equations \[28\], covariance matrices \[29\], etc. The rank obtained using PPACA is very close to the optimal rank as has been observed in \[24\] \[30\].

3.2. Obtaining the diffusion velocities

Now we will take advantage of the low-rank factorization of $V$ ($V = \epsilon LR^T$) in computing the diffusion velocities, i.e., for solving the linear system in Equation (16), which is obtained using Equations (7) and (10).

$$ (\text{diag}(VX) - \text{diag}(X)V) z = b $$

Equation (16) cannot be solved alone, since the system has a non-trivial null-space as discussed in the introduction. The flux criterion in Equation (5) also needs to be enforced along with Equation (16). The flux criterion in terms of $z_k$’s, instead of $v_k$’s is given by

$$ \sum_{k=1}^{N} W_k z_k = \sum_{k=1}^{N} W_k X_k \left( v_k + \frac{\nabla T D_k^{(T)}}{\rho T} Y_k \right) = \sum_{k=1}^{N} W_k X_k v_k + \sum_{k=1}^{N} W_k X_k \frac{\nabla T D_k^{(T)}}{\rho T} Y_k = \frac{W}{\rho T} \sum_{k=1}^{N} D_k^{(T)} $$

Hence, the flux criterion in terms of $z_k$’s is

$$ \sum_{k=1}^{N} W_k z_k = \frac{W}{\rho T} \sum_{k=1}^{N} D_k^{(T)} = \alpha $$

The Equations (16) and (18) can be combined into a single Equation (19).

$$ (\text{diag}(VX) - \text{diag}(X)V - SW^T) z = b - \alpha S $$

where $S \in \mathbb{R}^{N \times 1}$ is a random vector. Equation (19) can be rewritten as

$$ (D - PQ^T) z = b - \alpha S $$

where $D = \text{diag}(LR^T X) \in \mathbb{R}^{N \times N}$, $P = \begin{bmatrix} \text{diag}(X)L, & S \end{bmatrix} \in \mathbb{R}^{N \times (r+1)}$, $Q = \begin{bmatrix} R, & W \end{bmatrix} \in \mathbb{R}^{N \times (r+1)}$ and $r \ll N$.

The solution to Equation (20) is given by the Sherman-Morrison-Woodbury (SMW) formula \[31\] \[32\], i.e.,

$$ z = D^{-1}(b - \alpha S) + D^{-1}P(I - Q^TD^{-1}P)^{-1}Q^TD^{-1}(b - \alpha S) $$
The main thing to note with the SMW formula is that if we can solve a linear system efficiently, then low-rank updates to the linear system can also be solved efficiently. Once the vector \( z \in \mathbb{R}^{N \times 1} \) is obtained, the diffusion velocities \( v_k \)'s can be obtained by Equation (22).

\[
v_k = \begin{cases} \frac{z_k}{X_k} - \frac{\nabla T X_k}{\rho T Y_k} & \text{if } X_k \neq 0 \\ \frac{\nabla T X_k}{\rho T Y_k} & \text{if } X_k = 0 \end{cases}
\]

The pseudocode for computing \( v_k \)'s using Equations (21) and (22), along with the computational cost for each step, is presented in Algorithm 1. Note that the only dense matrix we are inverting is in the last step in Algorithm 1, i.e., we are inverting \((I - \mathcal{P})\), which is a small dense matrix of size \( \mathbb{R}^{(r+1) \times (r+1)} \).

**Algorithm 1** Pseudo code for computing diffusion velocities and computational complexity of each step; Note that the rank \( r \) of the matrix \( V \) is much smaller and is independent of \( N \), the size of the matrix \( V \).

| Step # | Computational step | Matrix/Vector type | Cost  |
|--------|--------------------|--------------------|-------|
| 1      | \( V = LR' \) using PPACA | Thin matrices \( L, R \in \mathbb{R}^{N \times r} \) | \( O(r^2N) \) |
| 2      | \( D = \text{diag}(LR'X) \) | Diagonal matrix \( D \in \mathbb{R}^{N \times N} \) | \( O(N) \) |
| 3      | \( P = [\text{diag}(X)L \ S] \) | Thin matrix \( P \in \mathbb{R}^{N \times (r+1)} \) | \( O(rN) \) |
| 4      | \( \alpha = \frac{W}{\rho} \sum_{k=1}^{N} D_k \) | Scalar \( \alpha \in \mathbb{R} \) | \( O(N) \) |
| 5      | \( b = D^{-1}(b - \alpha S) \) | Vector \( b \in \mathbb{R}^{N \times 1} \) | \( O(N) \) |
| 6      | \( P = D^{-1}P \) | Thin matrix \( P \in \mathbb{R}^{N \times (r+1)} \) | \( O(rN) \) |
| 7      | \( b = Q^T b \) | Vector \( b \in \mathbb{R}^{(r+1) \times 1} \) | \( O(rN) \) |
| 8      | \( z = b + \hat{P}^{-1} \hat{b} \) | Solution matrix \( z \in \mathbb{R}^{N \times 1} \) | \( O(rN + r^3) \) |
| 9      | \( v_k = \begin{cases} \frac{z_k}{X_k} - \frac{\nabla T X_k}{\rho T Y_k} & \text{if } X_k \neq 0 \\ \frac{\nabla T X_k}{\rho T Y_k} & \text{if } X_k = 0 \end{cases} \) | Diffusion velocities \( v_k \), where \( k \in \{1, 2, \ldots, N\} \) | \( O(N) \) |

4. Numerical benchmarks

4.1. Benchmark 1

For the same subsets of species considered in Section 2.2, based on the mechanism of Sarathy et al. [17], we consider a 1D multi-component diffusion problem on the interval \([-1, 1]\) with an imposed temperature and mass fraction profile. The pressure throughout the domain is kept constant to be the atmospheric pressure and the body forces are taken as zero. The interval is discretized into 1001 equally spaced grid points. The right hand side, which involves the gradients of the mass fractions are computed using second order central difference. The diffusion velocities are computed at all the 1001 grid points and the total time taken for this computation
using the fast algorithm and the conventional algorithm based on LU decomposition (Gaussian elimination) implemented using the linear algebra package Eigen [33] is shown in Figure 3(a).

From Figure 3(a) we see that even for a small number of species (224) the fast algorithm, for an accuracy of $10^{-6}$, is around 30 times faster than the conventional algorithm. Not surprisingly, the computational saving and advantage is more prominent for a large number of species. For instance, with 1794 species the fast algorithm, for an accuracy of $10^{-6}$, is around 2000 times faster than the conventional algorithm. Once the user input accuracy
is fixed, the accuracy of the solution is independent of the number of species as shown in Figure 3(b). Figure 4 presents the comparison our fast algorithm with the iterative biconjugate gradient proposed by Giovangigli [15]. We can clearly see that the computational cost of our proposed algorithm is orders of magnitude faster than the iterative method. In fact, the iterative method still scales as $O(N^3)$ albeit it is faster than the usual LU decomposition.

4.2. Benchmark 2

We also apply this algorithm to compute diffusion velocities of species involved in a jet fuel surrogate mechanism proposed by Narayanaswamy et al. [34], which has been developed in stages [35–38]. The temperature and species mass fractions profiles are obtained from a transient solution to a 1D premixed flame of a jet fuel surrogate. The simulation is performed at atmospheric pressure and unburnt temperature of 403K [34] in a computational domain of length 17.6mm (with 303 grid points) using FlameMaster [39]. The mechanism consists of 369 species. No body forces are considered. The time taken and accuracy in the diffusion velocities computed at all the grid points at a specific time instant for different input accuracies are provided in Table 1. Note that the fast algorithm, with an input accuracy of $10^{-6}$, is nearly 80 times faster than the conventional algorithm. The error in the solution is comparable with the input accuracy of the low-rank factorization of the matrix $V$.

| Input accuracy for PPACA ($\epsilon_{inp}$) | Time taken (in secs) | Relative error in solution ($\epsilon_{sol}$) |
|------------------------------------------|----------------------|---------------------------------------------|
| $10^{-6}$                                 | 0.34                 | $1.8 \times 10^{-9}$                        |
| $10^{-10}$                                | 1.01                 | $7.4 \times 10^{-10}$                       |
| $10^{-14}$                                | 1.94                 | $5.1 \times 10^{-15}$                       |

5. Conclusions

An accurate, fast, direct and robust algorithm to compute multi-component diffusion velocities has been proposed. To our knowledge, this is the first provably accurate algorithm (the solution can be obtained up to an arbitrary degree of precision) scaling at a computational complexity of $O(N)$ in finite precision. The key idea involves leveraging the fact that the matrix of the reciprocal of the binary diffusivities, $V$, is low rank, with its rank being independent of the number of species involved. The low rank representation of matrix $V$ is computed in a fast manner using PPACA algorithm [23, 24] at a computational complexity of $O(N)$ and the Sherman-Morrison-Woodbury [31, 32] formula is used to solve for the diffusion velocities. Rigorous proofs and numerical benchmarks illustrate the low rank property of the matrix $V$ and scaling of the algorithm. This method is being
incorporated in a droplet burning simulation, as a part of our ongoing work, where the diffusion velocities need to be computed accurately.

List of Algorithms

1 Pseudo code for computing diffusion velocities and computational complexity of each step; Note that the rank $r$ of the matrix $V$ is much smaller and is independent of $N$, the size of the matrix $V$. 10

List of Tables

1 Multi-component diffusion for a transient solution to a 1D premixed flame of a jet fuel surrogate. The total time taken for the fast algorithm includes computing the low-rank factorization using PPACA and obtaining the diffusion velocity using the SMW formula at all grid points. The relative error obtained is the maximum over all the grid points of the relative error of the solution measured using the $\|\cdot\|$. The diffusion coefficients are computed using inelastic molecular collisions. 12
