Persistence in coarsening 1D spin systems with a power law interaction \( r^{-1-\sigma} \) is considered. Numerical studies indicate that for sufficiently large values of the interaction exponent \( \sigma (\sigma \geq 1/2) \) in our simulations, persistence decays as an algebraic function of the length scale \( L \), \( P(L) \sim L^{-\theta} \). The Persistence exponent \( \theta \) is found to be independent on the force exponent \( \sigma \) and close to its value for the extremal \( (\sigma \rightarrow \infty) \) model, \( \bar{\theta} = 0.17507588 \ldots \). For smaller values of the force exponent \( (\sigma < 1/2) \), finite size effects prevent the system from reaching the asymptotic regime. Scaling arguments suggest that in order to avoid significant boundary effects for small \( \sigma \), the system size should grow as \([O(1/\sigma)]^{1/\sigma}\).

Coarsening dynamics of one-dimensional systems with a power-law \( V(r) \sim r^{-\sigma-1} \) interaction between spins has recently been studied by Lee and Cardy [3], and Rutenberg and Bray [4]. It had been established that after quenching from a high-temperature disordered phase to \( T = 0 \) these systems develop a domain structure characterized by a single lengthscale \( L(t) \). A naive argument based on the law of motion for domain walls, \( L \sim L^{-\sigma} \) (where \( L^{-\sigma} \) is a typical force between domain walls), produces an asymptotically correct time dependence of \( L \),

\[
L(t) \sim t^{1/1+\sigma}.
\]

Other properties of this system, including correlation functions and domain size distribution, have been studied in [3] as well.

In this paper we shall look at another facet of 1D phase-ordering systems with a power-law interaction: what fraction \( P \) of spins have never changed sign up to the time \( t \)? Or, equivalently, what fraction of the space has never been crossed by a domain wall? Such a property of coarsening systems is usually called persistence and has recently become a major subject of research in statistical physics [3,4]. Let us briefly review some known results in this field relevant to our problem. In [3] the exact solution was found for persistence in an ordering system with extremal dynamics. The extremal dynamics limit is reached by formally setting \( \sigma \rightarrow \infty \), which means that interactions become infinitely short-range. In this limit, coarsening proceeds by consecutive shrinking and disappearance of the current smallest domains in the system, while other domain boundaries remain virtually motionless. It was established in [3] that persistence at a stage of evolution when the average domain size is \( L \) is proportional to \( L^\theta \), where the exponent \( \theta = 0.17507 \ldots \) is the solution of an implicit integral equation.

In [3] persistence exponents have been calculated for coarsening 1D Potts models with Glauber dynamics. For the 2-state Potts (Ising) model, persistence decays as \( t^{-\theta} \), \( \theta = 3/8 \), or in terms of the average domain size \( L \), \( P(L) \sim L^{-3/4} \).

The following conclusion can be drawn from a comparison of persistence exponents for extremal and Glauber dynamics. Extremal dynamics is more efficient in preserving persistence, since the motion of domain walls is always directed towards their ultimate annihilation partners, while in the case of Glauber dynamics, domain walls perform random walks and sweep through a larger amount of space, which otherwise could have remained persistent. The extremal dynamics exponent \( \bar{\theta} \) sets a lower bound on persistence exponents for systems with a finite force exponent \( \sigma \). It is easy to visualize a scenario when a domain wall first moves away from its ultimate annihilation partner, and then, after the stronger force source disappears, it turns back. Such events result in spin flips on parts of the line that belong to a surviving domain and would have been left untouched in the extremal dynamics case.

The results presented below suggest that this lower boundary \( \bar{\theta} = 0.17507 \ldots \) is in fact the exact value of the persistent exponent for arbitrary \( \sigma > 0 \).

Let us formally introduce our model: We consider coarsening of the 1D 2-state spin system with a long-range ferromagnetic Hamiltonian:

\[
H = -\frac{4}{\sigma} \sum_{i>j} \frac{s_is_j}{(x_i-x_j)^{\sigma+1}}.
\]

After quenching from a high-temperature random phase to \( T = 0 \), coarsening dynamics for this system is determined by the motion of domain walls, governed by the Langevin equation. The velocity of a wall is equal to the sum of pairwise forces from other walls, with walls of the same signs repelling and walls of the opposite signs attracting each other:

\[
\frac{dr_i}{dt} = \sum_{j \neq i} (-1)^{i+j} \text{sign}(r_i - r_j) F_{ij}
\]

\[
F_{ij} = \frac{1}{|r_i - r_j|}.
\]
When the adjacent walls meet, they annihilate. As we mentioned, the degree of coarsening is uniquely characterized by a typical domain size $L(t) \sim t^{1/(1+\sigma)}$. We measure the fraction of space $P(L)$ that has never been crossed by a single domain wall as a function of this lengthscale $L(t)$. We perform molecular dynamics simulations of the model for the following values of the force exponent: $\sigma = 3/2, 5/4, 1, 3/4, 1/2, 1/4$. Each run starts with a system consisting of $N_0 = 100000$ domain walls; results for each $\sigma$ are averaged over 20 initial configurations. Open boundary conditions with no replicas added to the boundaries are used. To speed up the evaluation of forces, a 1D multipole expansion has been performed, and terms of up to quadrupole order have been taken into account.

The results for persistence as a function of the average domain length $L$ are presented in log-log form in Fig. 1. Except for small force exponents ($\sigma = 1/4$ and later evolution stages for $\sigma = 1/2$) all the curves collapse at a line with a slope $\approx -0.175$, which corresponds to $\sigma = \infty$ extremal model.

Statistical error bars are shown in Fig. 2 for a single set of data ($\sigma = 5/4$).

Our simulations suggest that scaling of persistence, corresponding to $\sigma = \infty$, is valid for all other not very small $\sigma$. The following asymptotic argument helps to understand why this is so. At any current moment of time, persistent spins are mostly contained in the domains that were expanding at almost all previous stages of coarsening; i.e. these domains were larger than the average at those stages. If one of such large domains is surrounded by two small neighbors, it would most probably grow outwards, and no spin flips, additional to those inevitably caused by directed coarsening itself, would happen. The situation may be different if two or three big domains are adjacent to each other: their domain walls may wonder and get inside the territory of the future survivor, causing some excessive spin flips.

*Fig. 1.* The log-log plot of persistence $P(L)$ vs. average domain size $L$ for various force exponents $\sigma$. The straight line corresponds to $P(L) \sim L^{-\eta}$.

![Fig. 2](image2.png)

*Fig. 2.* The log-log plot of persistence $P(L)$ vs. average domain size $L$ force exponents $\sigma = 5/4$ with statistical error bars. The straight line corresponds to $P(L) \sim L^{-\theta}$.

We can estimate the characteristic scale of such a persistence-loosing event. A typical distance $\Delta L$ that a wall of domain of size $L_0$, surrounded by a group of domains of similar sizes, travels during time $t$ is

$$\Delta L \sim L_0 - (L_0^{(1+\sigma)} - t)^{1+\sigma} \approx L_0 \left[ \frac{L(t)}{L_0} \right]^\sigma. \quad (5)$$

Here $L(t) \sim t^{1/(1+\sigma)}$ is the average domain size at time $t$. For positive $\sigma$, $\Delta L$ becomes negligible compared to $L$ when $L(t)/L_0 \gg 1$, hence the number of spin flips additional to those present in extremal dynamics coarsening scenario becomes negligible. Another conclusion that follows from Eq. (5) is that for small $\sigma$, the crossover time to $P(L) \sim L^\theta$ scaling must be larger since the system must develop structure that includes sufficiently large domains.

However, besides long intitial transitional times, there is another reason for the breakdown of scaling for small $\sigma$ that we observed in our simulations. Let us first consider the opposite to $\sigma = \infty$ case of $\sigma = 0$. In this limit forces, are distance-independent, and domain wall dynamics is described by the equation

$$\frac{dr_i}{dt} = \sum_{j \neq i} (-1)^{i+j} \text{sign}(r_i - r_j). \quad (6)$$

Since domain walls come in pairs, the sum in Eq. (6) is equal to $\pm 1$. That means that all walls have the same constant velocity with odd-number walls moving to the left and even-number moving to the right. The whole system becomes a collection of independently collapsing and growing domains. This clearly violates the scaling (1): in fact the $\sigma = 0$ system has two length scales, $L_0 - 2vt$ and $L_0 + 2vt$, where $L_0$ is the average initial
domain length and $v = 1$ is the velocity of domain walls. For an
exponential distribution of initial domain sizes, $W(L_0) = \exp(-L_0)$, persistence can be expressed as
\[
\tilde{P}(t) = \frac{\int_0^\infty W(x)dx + \int_{2\otimes}^\infty W(x)dx}{2 \int_0^\infty W(x)dx} = \frac{1 + \exp[-2t]}{2} \quad (T)
\]
Systems with few particles and small $\sigma$ coarsen almost
due to the $\sigma = 0$ scenario: particles across the whole
system feel the presence of the boundary. Odd
and even-number walls tend to move predominantly to
the left and right, respectively, independent of the posi-
tion of their nearest neighbors.

To probe whether the deviation from $P(L) \sim L^\theta$ scal-
ing in persistence behavior is caused by $\sigma = 0$ finite size
effects, we do the following measurements. First, for the
system of the same initial size ($N = 10^5$) we plot the
average domain length $L(t)$ as a function of time and
compare it to the $L \sim t^{1/1+\sigma}$ prediction.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig3.png}
\caption{The log-log plot of average domain size $L(t)$ vs. time for various force exponents $\sigma$. Straight lines correspond to scaling predictions, $L(t) \sim t^{1/1+\sigma}$.}
\end{figure}

Results for this simulation are presented in Fig. 3. One
can see that the system with $\sigma = 1/4$ is never in scaling
 regime, system with $\sigma = 1/2$ behaves according to
only up to some intermediate stage of evolution. For
all other force exponents $\sigma > 1/2$, for a certain period
of evolution after short transitional time, typical domain
sizes scale according to (1). Another check of whether
a system feels the presence of the boundaries and there-
fore crosses over to the $\sigma = 0$ coarsening regime, is to
measure directly the fraction of domain walls $B(L)$ that
move opposite to the direction prescribed by boundary
effects. In Fig. 4 we plot the fraction of even-number do-
main walls moving to the right and odd-number domain
walls moving to the left for the systems initially consist-
ing of the same number of domains, $N = 10^5$. For finite
$\sigma > 0$ and a truly infinite system this fraction should
be equal to $1/2$, for $\sigma = 0$ it should be 0. We observe
that our system is never in the true infinite-size regime
for $\sigma = 1/4$, finite size effects are becoming evident for
$\sigma = 1/2$, even at early stages of evolution, and only for
$\sigma \geq 3/4$ the boundary effects could be neglected.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig4.png}
\caption{Number of domain walls $B(L)$ that move opposite
to the direction prescribed by boundary effects vs. average
domain length $L$ for various force exponents $\sigma$.}
\end{figure}

Finally, we present a rough estimate of how big a sys-
tem should be for a particular value of $\sigma \ll 1$ to avoid
significant finite-size effects. We evaluate a force $F_{1-2}$,
exerted on a test domain wall by a dipole pair of neigh-
oring domain walls,
\[
F_{1-2} \approx \left( \frac{1}{L} \right)^\sigma - \left( \frac{1}{2L} \right)^\sigma = \left( \frac{1}{L} \right)^\sigma (\sigma \ln 2 + \mathcal{O}(\sigma^2)) \quad (8)
\]
and compare it to the force $F_N$ exerted on the same test
domain wall by a single domain wall at the the system
boundary.
\[
F_N \approx \left( \frac{2}{NL} \right)^{\sigma} \quad (9)
\]
Here $L$ and $N$ are the typical domain length and the
number of domains in the system. The boundary effects
become significant when these forces are of the same or-
der. Hence for particular $\sigma$, the minimum number of
particles to avoid finite size effects $N_{\text{min}}$ is
\[
N_{\text{min}} \approx 2 \left( \frac{1}{\sigma \ln 2} \right)^\frac{1}{\sigma} \quad (10)
\]
We have observed (see Fig. 4) that for $\sigma = 1/2$, $N_{\text{min}} \approx 10^5$. Assuming the following parameterization of minimal
size of the system for small $\sigma$, $N_{\text{min}} = (\text{constant}/\sigma)^{1/\sigma}$
and fitting it to $N_{\text{min}}(\sigma = 1/2) = 10^5$, we obtain
$N_{\text{min}}(\sigma = 1/4) \approx 1.6 \times 10^{11}$. This is well beyond the
limits of computational power available to us.

In summary, we presented numerical evidence and a
scaling argument suggesting the universality of persis-
tent exponent for extremal model, $\theta = 0.17507588\ldots$
for models with arbitrary force exponents $\sigma > 0$. We found that a deviation from scaling for persistence, that happens for small $\sigma$, is accompanied by a similar deviation from scaling for a typical domain size $L(t)$ and is caused by finite size effects that cause crossover to a $\sigma = 0$ coarsening scenario. We estimated that in order to avoid boundary effects, the system size should grow as $[O(1/\sigma)]^{1/\sigma}$. A possible extension of this work is for higher dimensional systems, though the duality between domain walls and spin dynamics that was extensively used for this work, may not be so straightforward to apply.
