Abstract

Aims Acute myocardial infarction (AMI) is associated with left ventricular remodelling (LVR), which leads to progressive heart failure. Platelets play a pivotal role in promoting systemic and cardiac inflammatory responses during the complex process of myocardial wound healing or repair following AMI. This study aimed to investigate the impact of platelet reactivity immediately after primary percutaneous coronary intervention (PCI) on LVR in AMI patients with ST-segment (STEMI) and non-ST-segment elevation (NSTEMI).

Methods and results This prospective, single-centre, observational study included 182 patients with AMI who underwent primary PCI (107 patients with STEMI and 75 patients with NSTEMI). Patients were administered a loading dose of aspirin plus prasugrel before the procedure, and platelet reactivity was assessed using the VerifyNow P2Y12 assay immediately after PCI. Echocardiography was performed before discharge and during the chronic phase (8 ± 3 months after discharge). LVR was defined as a relative ≥20% increase in left ventricular end-diastolic volume index (LVEDVI). LVR in chronic phase was found in 34 patients (18.7%) whose platelet reactivity was significantly higher than those without LVR (259.6 ± 61.5 and 213.1 ± 74.8 P2Y12 reaction units [PRU]; P = 0.001). The occurrence of LVR did not differ between patients with STEMI and patients with NSTEMI (21.5% and 14.7%; P = 0.33). The optimal cut-off value of platelet reactivity for discriminating LVR was ≥245 PRU. LVEDVI significantly decreased at chronic phase in patients without high platelet reactivity (<245 PRU) (from 49.2 ± 13.5 to 45.4 ± 15.8 mL/m²; P = 0.02), but not in patients with high platelet reactivity (≥245 PRU) (P = 0.06). Multivariate logistic analysis showed that high platelet reactivity was an independent predictor of LVR after adjusting for LVEDVI before discharge (odds ratio, 4.13; 95% confidence interval, 1.85–9.79).

Conclusions High platelet reactivity measured immediately after PCI was a predictor of LVR in patients with AMI during the chronic phase. The role of antiplatelet therapy on inflammation in the myocardium is a promising area for further research.

Keywords Myocardial infarction; Left ventricular remodelling; Platelet reactivity; Inflammation; Reverse remodelling; Prasugrel

Introduction

Although mortality after myocardial infarction (MI) has declined, the prevalence of post-MI heart failure (HF) continues to increase.1 The development of the HF phenotype in these patients arises from a complex, progressive, molecular, and cellular transformation called ‘left ventricular remodelling (LVR).2 Moreover, some studies have shown that LVR that occurs after MI is related to long-term morbidity and mortality.1 Therapeutic interventions such as early reperfusion therapy and optimal medical therapy with neurohormonal antagonists have been developed to reduce infarct size
and attenuate LVR development and progression. However, a preventive strategy for LVR has not yet been established.

Platelets play a pivotal role in promoting systemic and cardiac inflammatory responses during the complex process of myocardial wound healing or repair following MI, which can cause LVR and cardiac rupture. The REMODELLING (Role of Platelet Reactivity in LV Remodelling after ST-Segment Elevation Myocardial Infarction) trial first suggested a relationship between platelet reactivity 3 days after percutaneous coronary intervention (PCI) as well as the risk for subsequent LVR in patients with ST-segment elevation myocardial infarction (STEMI) during clopidogrel treatment. Furthermore, the HEALING-AMI (High Platelet Inhibition with Ticagrelor to Improve Left Ventricular Remodelling in Patients With ST-Segment Elevation Myocardial Infarction) study showed ticagrelor, a potent oral P2Y12 inhibitor, was superior to clopidogrel for LVR after reperfusion of STEMI with primary PCI. However, in these studies platelet reactivity was not assessed immediately after PCI, when platelet aggregation may have been increased by various invasions, including angioplasty. Furthermore, little is known about the association between platelet reactivity and LVR in patients with non-ST-elevation myocardial infarction (NSTEMI), because previous studies have focused on patients with STEMI. In addition, no study has investigated the association between platelet reactivity immediately after PCI and evaluated structural changes in the LV using echocardiography.

Herein, the aim of this study is to investigate the impact of platelet reactivity immediately after primary PCI on LVR and echocardiographic changes in the chronic phase in patients with AMI, including STEMI and NSTEMI.

**Methods**

This prospective, single-centre, observational study was performed from January 2016 to June 2021. The study was approved by the ethics committee of Okayama City Hospital. All participants provided written informed consent prior to enrolment. All procedures were conducted in accordance with the Declaration of Helsinki and its amendments. This study was registered in the UMIN Clinical Trials Registry (UMIN-000029729).

**Patient population**

Patients who were hospitalized for STEMI or NSTEMI and who underwent primary PCI were prospectively enrolled. Definitions of STEMI and NSTEMI were determined according to appropriate guidelines. Briefly, STEMI was diagnosed based on elevated levels of biomarkers for myocardial necrosis (including troponin T, troponin I, or creatine kinase muscle/brain), with ST-segment elevation of 1 mm or more in at least two contiguous ECG leads; NSTEMI was defined as elevated cardiac troponin I (cTnI) and symptoms of ischemia, without ST-segment elevation.

The exclusion criteria were as follows: (i) age <18 years; (ii) death during hospitalization; (iii) lack of platelet reactivity data; (iv) lack of appropriate echocardiographic data during hospitalization (cases in which the echocardiographic data were not appreciable for evaluation due to unclear images, or the images were not saved because of the use of portable ultrasonography); and (vi) cases with echo data outside the follow-up period (8 ± 3 months), or cases where echocardiographic follow-up was not performed.

The flow diagram of this study is presented in Figure 1. A total of 349 patients with AMI who underwent index PCI between January 2016 and June 2021 were identified from the hospital. After screening, 182 patients were included in the study. Platelet reactivity could not be measured in 36 patients because of hemodynamic instability or urgent treatment. Moreover, there were no available echocardiographic data in 32 patients, and 8 patients died during hospitalization. Therefore, these patients were excluded, and 273 patients remained in the initial cohort. Of these, appropriate echocardiographic data could not be acquired in 42 patients. Additionally, 49 patients could not undergo echocardiography within the designated period (8 ± 3 months) because of deterioration in activities or hospitalization in other institutions. The remaining 182 participants were enrolled in the study.

**Procedure**

All PCI procedures were performed according to standard techniques, and the stent type was chosen by the operator after coronary angiography. We enrolled patients with AMI undergoing primary PCI for an infarct-related artery located in the proximal or midportion of a major epicardial coronary artery. In all cases, the loading doses of prasugrel (20 mg) and aspirin (200 mg) were administered in the cardiac catheter laboratory after diagnostic coronary angiography, and prasugrel (3.75 mg daily) and aspirin (100 mg daily) were subsequently administered as maintenance doses according to the guideline of the Japanese Circulation Society. In most patients, dual antiplatelet therapy was continued for 6 months. At the discretion of the attending physician, certain patients were prescribed oral anticoagulants instead of aspirin, or were switched from prasugrel to clopidogrel at discharge, according to their co-morbidity or bleeding risk. All patients were treated with guideline-recommended optimal pharmacological therapy, including beta-blockers, angiotensin blockers, and statins. Echocardiographic values during hospitalization and 8 ± 3 months after discharge were compared.
Echocardiographic measurement and definition of left ventricular remodelling

Echocardiographic images were obtained before discharge in accordance with current European and American guidelines.\textsuperscript{12,13} Echocardiography was performed using commercially available equipment (EPIQ 7G Ultrasound System, Philips Japan, Tokyo, Japan) before discharge and at the follow-up visit. Echocardiographic recordings were performed by three experienced echocardiographers who were blinded to biomarker values. LV end-systolic and end-diastolic volume indices (LVESVI and LVEDVI, respectively) were calculated by dividing LVESV and LVEDV by body surface area, as the reference values of LV volumes are significantly influenced by body mass.\textsuperscript{13} Left atrial (LA) volume was measured using the biplane method of disks using apical four- and two-chamber views at the LV end systole. The LA volume index (LAVI) was calculated by dividing the absolute LA volume by body surface area. Diastolic LV function was assessed by measuring the ratio between the peak mitral flow velocity in the early rapid filling phase (E) and the average peak early diastolic mitral annulus velocity (e'). Non-infarction-related segments were selected to obtain e'. The modified Simpson’s rule was given priority in the measurement of LVEF, LVESVI, and LVEDVI, and the M mode was used when the measurement was not performed according to the modified Simpson’s rule.

The LV remodelling index was calculated as the relative change in LVEDVI observed in the chronic phase compared with that at baseline. LVR was defined as a relative increase in LVEDVI $\geq 20\%$.\textsuperscript{7} Patients were divided into LVR and non-LVR groups according to presence or absence of LVR in the chronic phase.

Laboratory measurement and assessment of platelet reactivity

Baseline biochemical assessments were performed before the index procedure. Platelet function in response to prasugrel was assessed using the VerifyNow P2Y12 assay (International Technidyne Corporation, Edison, NJ, USA), according to the manufacturer’s instructions.\textsuperscript{14} Blood samples were collected once per procedure from the artery immediately before sheath removal following PCI. VerifyNow P2Y12 is a whole-blood point-of-care assay that measures responsiveness to P2Y12 antagonists. The cartridge contained fibrinogen-coated polystyrene beads, 20 $\mu$M ADP, and 22 nM prostaglandin E1; the optical signal of this channel was reported as P2Y12 reaction units (PRU; range, 0–550).\textsuperscript{15}

Statistical analysis

Categorical variables are presented as numbers (%). Normally distributed continuous variables are shown as the mean $\pm$ standard deviation and were compared between groups using Student’s $t$-test. Continuous variables that were not normally distributed are shown as medians with interquartile ranges and were compared using the Mann–Whitney $U$ test. The association between continuous variables was investigated using Pearson’s correlation coefficient. Receiver operating characteristic curve analysis was performed to obtain an ideal cut-off for PRU to discriminate the presence of LVR, which was determined as the value providing the greatest sum of sensitivity and specificity. Univariate and multivariate logistic analyses were used to identify the significant factors associated with the primary endpoint. Multivariate
Results

Baseline characteristics and incidence of left ventricular remodelling

The demographic and clinical characteristics of patients are presented in Table 1. The mean age of the study population was 68.2 years, and 78.6% of patients were men. The prevalence of hypertension and diabetes was 67.6% and 33.0%, respectively. The follow-up duration was 7.2 ± 1.7 months. LVR was observed in 18.7%, or 34 cases. LVR occurred in 21.5% (n = 23) among 107 STEMI patients, and in 14.7% (n = 11) among 75 NSTEMI patients, with no statistically significant difference between patients with STEMI and NSTEMI (P = 0.332). There were no differences in age, sex, or blood pressure between the LVR and non-LVR groups. The LVR group had higher platelet reactivity (P = 0.001) than the non-LVR group, whereas laboratory characteristics, except for platelet reactivity, did not differ between the two groups.

In addition, there were no significant differences in co-morbidities, PCI-related characteristics, or medication at discharge between the two groups. The proportion of patients with TIMI 3 did not differ between the two groups (P = 0.849). Regarding echocardiographic parameters, LVEDVI in the LVR group was significantly higher than that in the non-LVR group (P = 0.008), while there was no difference in other parameters, including LVMi, LVEF, LVESVI, LAVI, and E/e′, between these two groups.

Association of high platelet reactivity and changes in echocardiographic parameters

A Pearson’s correlation analysis demonstrated that platelet reactivity at baseline was significantly associated with changes in LVEDVI (r = 0.23, P = 0.002), LVESVI (r = 0.17, P = 0.020), and LVMi (r = 0.15, P = 0.046). In contrast, LVEF (r = –0.11, P = 0.122), LAVI (r = 0.10, P = 0.184), and E/e′ (r = 0.08, P = 0.261), were not significantly associated. The optimal cut-off value of platelet reactivity for discriminating LVR by using receiver operating characteristic curve analysis was 244.5 PRU, with a sensitivity of 0.706 and a specificity of 0.655 (AUC: 0.689; 95% CI: 0.595 to 0.783). Therefore, we set the cut-off value for platelet reactivity that defined high platelet reactivity (HPR) as ≥245 PRU. HPR was found in 75 patients (41.2%) among all patients.

A comparison of echocardiographic parameters before discharge and during the chronic phase is shown in Figure 2. In the HPR group, LVEF was significantly increased in the chronic phase (58.3 ± 10.9% vs. 60.6 ± 11.6%; P = 0.013), while LVEDVI, LVESVI, LAVI, LVMi, and E/e′ did not change significantly. In contrast, in the non-HPR group, LVEF was increased significantly [60.3 ± 11.8 vs. 62.9 ± 11.5 (%); P = 0.005], and LVEDVI [49.2 ± 13.5 vs. 45.4 ± 15.8 (mL/m²); P = 0.020], LVESVI [20.0 ± 10.1 vs. 16.8 ± 8.8 (mL/m²); P < 0.001], LAVI (28.0 ± 8.3 vs. 26.3 ± 9.1, P = 0.070), LVMi (106.9 ± 27.2 vs. 98.9 ± 27.4, P = 0.003), and E/e′ (13.4 ± 4.2 vs. 11.9 ± 3.8, P < 0.001), were significantly decreased.

Table 2 shows the change in echocardiographic parameters in patients with STEMI and NSTEMI. In patients with STEMI, LVEF was increased, and LVEDVI, LVESVI, and E/e′ were decreased significantly in the non-HPR group, while LVEF only improved in the HPR group. Similarly in patients with NSTEMI, LVESVI, LVMi, LAVI, and E/e′ were decreased significantly in the non-HPR group, while LVMi only decreased in the HPR group. However, LVEF did not improve significantly in both groups.

Impact of high platelet reactivity on left ventricular remodelling

The logistic analysis of the predictors of LVR is shown in Table 3. The univariate logistic analysis demonstrated that the presence of LVR was significantly associated with LVEDVI (odds ratio, 4.56; 95% confidence interval, 2.08–10.7; P < 0.001) and HPR (odds ratio, 0.95; 95% confidence interval, 0.92–0.99; P = 0.009). The multivariate logistic analysis also showed that the presence of LVR was significantly associated with LVEDVI (odds ratio, 0.96; 95% confidence interval, 0.92–0.99; P = 0.026) and HPR (odds ratio, 4.13; 95% confidence interval, 1.85–9.79; P < 0.001).

Discussion

To our knowledge, this is the first study to evaluate the association between platelet reactivity immediately after primary PCI with LVR and each echocardiographic parameter in patients with AMI, including STEMI and NSTEMI. We found that in patients with AMI, HPR (e.g. PRU ≥ 245) measured immediately after primary PCI was an independent predictor of LVR, with patients with HPR having an approximately 4.13-fold greater risk of LVR.

Previous studies have reported a negative impact of activated platelets on adverse cardiac events, suggesting that HPR is significantly and independently associated with cardiovascular death and major adverse coronary events in patients with acute coronary syndrome (ACS) undergoing PCI. HPR was also a prognostic factor for cardiovascular events in patients with stable angina, and a recent report also showed that HPR is associated with long-term mortality in
## Table 1 Baseline characteristics

| Age, years | All (n = 182) | LVR (n = 34) | Non-LVR (n = 148) | P-value |

patients with stable angina and ACS. However, the effect of platelet reactivity after PCI on cardiac function in the chronic phase has not been fully investigated. The REMODELLING trial was the first to show the association between platelet activation and the LVR process in patients with STEMI and clopidogrel loading. Our study adds new insights to the results of the REMODELLING trial by showing the relationship between HPR and LVR, with the difference that prasugrel was administered instead of clopidogrel and that both STEMI and NSTEMI were included. Moreover, the fact that low platelet reactivity immediately after PCI predicted preferable cardiac function in the chronic phase was a remarkable finding.

Notably, this result was not limited to STEMI patients, but was also observed in those with NSTEMI in this study.

Table 2: Change in echocardiographic parameters in acute versus chronic phase, for HPR and non-HPR respectively

| STEMI (n = 107)       | HPR (n = 50) | P-value | Non-HPR (n = 57) | P-value |

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BNP, brain natriuretic peptide; CPK, creatine phosphokinase; HbA1c, glycated haemoglobin; HPR, high platelet reactivity; hsCRP, high-sensitivity C-reactive protein; LVEDVI, left ventricular end-diastolic volume index; LVESVI, left ventricular end-systolic volume index; STEMI, ST-elevation myocardial infarction; PRU, P2Y12 reaction units.

Previously studies have shown that prasugrel and ticagrelor achieve platelet inhibition earlier and maintain it lower for a longer period than clopidogrel does.22,23 The difference in the effect of prasugrel and ticagrelor on platelet reactivity remains unclear; however, both drugs seem to be superior to clopidogrel in lowering PRU effectively. In the HEALING-AMI study, platelet reactivity was measured before the PCI procedure (immediately after sheath insertion) in the acute phase, and was not found to be significantly different between the clopidogrel and ticagrelor groups.7 However, that study suggested that PRU values at discharge and 30 days after PCI were significantly different between the two groups, and that ticagrelor was superior to clopidogrel for LVR. Both prasugrel and ticagrelor have been shown to sufficiently suppress platelet reactivity approximately 2 h after oral loading dose administration.22 In addition, previous studies showed that cytochrome P-450 genetic variants did not affect inhibition of platelet aggregation in patients treated with prasugrel.24,25 Meanwhile, platelet reactivity has been demonstrated to be affected by PCI.8,9,26 We also reported that an increase in platelet reactivity just after elective PCI was associated with increased risk of PCI-related myocardial infarction.26 Additional studies showed that platelets are activated during PCI due to regional endothelial dysfunction caused by ischemia or by iatrogenic reasons.8,9 Considering that high platelet activity influences the inflammatory status, we hypothesized that LVR may be affected by a condition with high platelet reactivity after PCI induced by both the acute myocardial infarction and the PCI procedure. Therefore, timing sample collection immediately after PCI should be appropriate for determining whether platelet function is effectively suppressed.

This study added new insights to the literature by including patients with NSTEMI and improved echocardiographic parameters in the chronic phase, regardless of STEMI or NSTEMI in non-HPR patients. However, LVEF and LVEDVI did not improve in patients with NSTEMI, regardless of platelet reactivity. One possible explanation for this is that the duration from the onset to PCI varied among patients with NSTEMI because some patients were not referred to the hospital soon after the onset. In such cases, CPK often peaked upon the patient’s arrival at our hospital. In contrast, minimal cardiac injury is likely to be more common in NSTEMI than in STEMI cases. We considered this to be the main reason that LVEF did not improve in patients with NSTEMI, and there was no association between peak CPK value and the occurrence of LVR in this study. It has been reported that delayed reperfusion therapy is associated with LVR,27 and it may be also associated with strong myocardial inflammation despite relatively low peak CPK values.

Regarding the underlying mechanisms between platelet reactivity and LVR, inflammation may have a critical role. The inflammatory response after an infarct event results in the formation of an extracellular matrix by fibroblasts, and persistent and exaggerated inflammatory responses after infarct events contribute to infarct expansion and LVR.28,29 Platelets contribute to inflammatory responses through two fundamental mechanisms5: granular release of inflammatory mediators, such as serotonin, histamine, chemokines, cytokines, and MMPs; and platelet-leukocyte interaction, contributing to activation of leukocytes and recruitment to inflamed tissues, which is mainly mediated by P-selectin/PSGL-1.5,30 Treatment with a P2Y12 inhibitor suppresses the proportion of P-selectin-expressing platelets and inhibits platelet-leukocyte interactions.5 It remains unclear whether suppressing platelet reactivity directly inhibits myocardial remodelling and improves patient prognosis, while several animal studies have suggested that P2Y12 inhibitors limit LVR myocardial infarct size and LVR progression.5,31 In the present study, LVR was suppressed in patients without HPR and cardiac function was improved in the chronic phase, suggesting that platelet reactivity may be a marker of cardiac function.
in the chronic phase. The increase in C-reactive protein, a marker of inflammation, was reported to be associated with the development of heart failure in patients after AMI, although it cannot be a therapeutic target. The potential for potent P2Y12 inhibitors to suppress activated platelet reactivity, subsequent inflammation, and LVR, especially after PCI in patients with AMI, may be a new focus for chronic HF for which further studies are required.

Low platelet reactivity in the acute phase could predict less LVR development in the chronic phase and preferable cardiac function, which may explain the previously reported occurrence of cardiovascular events and poor prognosis in patients with HPR. Therefore, HPR immediately after PCI may provide a reason for the earlier and more intensive administration of such medications, and for closer follow up, in order to prevent LVR. Moreover, it is important to suppress platelet reactivity as strongly as possible during PCI. Acute antiplatelet effects should be considered in the future as a novel approach to suppress myocardial remodelling in the chronic phase. P2Y12 inhibition against LVR may be a promising area for further research investigating factors that improve the prognosis of patients with AMI.

Limitations

First, this study involved a relatively small number of patients and was conducted at a single centre. In addition, patients with unstable hemodynamic condition on admission and no available echocardiographic data, as well as patients who died during hospitalization, were excluded. Therefore, it cannot be denied that selection bias has affected the results. Second, we only assessed platelet reactivity immediately after the PCI procedure and did not follow-up on residual platelet reactivity during treatment. However, a single measurement may not be sufficient to clarify the relationship between platelet reactivity and LVR. Hence, serial measurement of platelet reactivity are required to clarify the optimal timing of platelet reactivity. Third, we evaluated platelet reactivity using VerifyNow, although other tests to measure platelet function have also been developed. Further study using additional tests will be needed to better understand the mechanistic background of platelet activity and LVR. Fourth, in this study, the impact of STEMI or NSTEMI on the association of HPR with LVR was not statistically significant, probably due to the limited number of LVR. To confirm this, larger studies are warranted. Finally, there were some cases in which adherence to pharmacological therapy could not be followed.

Given the above, further prospective studies with larger numbers of patients and longer follow-up periods are needed to confirm the findings of this study.

Conclusions

HPR immediately after PCI (platelet reactivity ≥245 PRU) was associated with the incidence of LVR in the chronic phase of AMI. Platelet reactivity in the acute phase may be a potential biomarker for predicting cardiac function in the chronic phase following an ischemic event. The role of antiplatelet therapy after ischemic events and its effect on inflammation in the myocardium are promising areas for further research.
