Abstract: This study aims to provide a thermophysical characterization of a new economical and green mortar. This material is characterized by partially replacing the cement with recycled soda lime glass. The cement was partially substituted (10, 20, 30, 40, 50 and 60% in weight) by glass powder with a water/cement ratio of 0.4. The glass powder and four of the seven samples were analyzed using a scanning electron microscope (SEM). The thermophysical properties, such as thermal conductivity and volumetric specific heat, were experimentally measured in both dry and wet (water saturated) states. These properties were determined as a function of the glass powder percentage by using a CT-Meter at different temperatures (20 °C, 30 °C, 40 °C and 50 °C) in a temperature-controlled box. The results show that the thermophysical parameters decreased linearly when 60% glass powder was added to cement mortar: 37% for thermal conductivity, 18% for volumetric specific heat and 22% for thermal diffusivity. The density of the mortar also decreased by about 11% in dry state and 5% in wet state. The use of waste glass powder as a cement replacement affects the thermophysical properties of cement mortar due to its porosity as compared with the control mortar. The results indicate that thermal conductivity and volumetric specific heat increases with temperature increase and/or the substitution rate decrease. Therefore, the addition of waste glass powder can significantly affect the thermophysical properties of ordinary cement mortar.

Keywords: soda lime waste glass; composite mortar; thermal conductivity; volumetric specific heat; effect of temperature

1. Introduction

The building construction industry is currently experiencing remarkable growth in the manufacturing of building materials. Concrete is produced with different compositions of ingredients based on the strength and performance requirements of the structure. The most commonly-used concrete is Normal Strength Concrete (NSC). The primary components of concrete are the binder or cement, fine aggregates, coarse aggregates, and water. In order to attain high strength or high performance standards, certain secondary components such as fly ash, ground granulated blast furnace slag (slag), silica fume, and superplasticizers are added to the design mix [1].
Cement mortar contains cement as a binder, sand as fine aggregate, water, and in some cases admixture. Next to concrete, mortar is also in high demand, as it ensures the bonding of masonry walls and provides thermal and phonic insulation. Portland cement (hydraulic binder) is the raw material used in manufacturing mortar. However, this material consumes large quantities of natural resources (limestone and clay) and generates a great amount of carbon dioxide during the preparation of clinker. Hence, the challenge of the entire industry is to reduce the consumption of cement by developing new ecological materials that are more efficient in mechanical and thermal terms.

Recently, the use of waste or by-products to produce sustainable building materials has been the subject of many studies due to their economic, environmental, and technical advantages. Replacing cement and/or sand with sustainable materials produces a sustainable cement mortar or even concrete [2–7]. Over the past two decades, recycling glass waste as a component of building material has been the subject of several studies [8–19].

These studies have shown that glass powders are used in manufacturing mortar and concrete because of the chemical and physical compatibility of sand. Jani and Hogland [8] have shown that the pozzolanic properties of glass increase with the decrease in the size of glass particles. Furthermore, the fine particles of glass favor a rapid pozzolanic reaction compared to slower alkali silica reaction (ASR) [20–23]. The chemical composition of glass also plays a very important role in the development of the pozzolanic reaction, the decrease in the rate of RAS reactions and, subsequently, influences the physical and mechanical properties of glass waste materials [24]. It follows that the choice of the type of glass must be made according to the amount of glass formers and glass stabilizers, which must be high compared to that of glass modifiers.

Regarding the mechanical properties of concrete and mortar based on powdered glass waste, it has recently been shown that cement mortar made with 60% recycled green glass powder has bigger pores due to the dilution. Chemical shrinkage and heat assessment show that the high glass powder replacement of cement paste increases the hydration reaction rate. Compressive strength and dynamic Young’s and shear moduli values decrease with increasing glass powder content especially for mortar made with 60% glass powder. Significant compressive strength is gained between 7 and 90 days for mortar with glass powder, especially with a 60% replacement showing pozzolanic reaction taking place during this period [10].

Du and Tan [12] evaluated properties of high-volume glass powder concrete (up to 60%). Beyond a replacement of 30%, calcium hydroxide became insufficient for the pozzolanic reaction of glass powder. The amount of calcium hydroxide decreased significantly at 45 and 60%, which shows that all the calcium hydroxide formed was consumed during the pozzolanic reaction. However, the composite concrete retained distinct resistance against water and chloride ingress.

In another study where mixtures contained 30% GP, the concrete strength at 404 days exceeded the target strength and reached up to 55 MPa [25].

The results from studies presented above reinforce the use of glass as a supplement in building materials. However, several researchers are interested in the studying thermal properties of concrete and/or mortar [26–28]. The thermal properties of building materials, including thermal conductivity, volumetric specific heat, and thermal diffusivity have a substantial effect on the energy consumption of buildings. The thermal properties of mortar and concrete can play an important role in the sustainability of buildings [2].

Experiments have shown that cement incorporated with 20% glass powder has lower thermal conductivity and specific heat than that of ordinary cement [20]. It should be noted that all thermal properties must be considered to prepare favorable living conditions. However, in most available studies, only the thermal conductivity and the specific heat of the material were evaluated. Until now, the study of the thermal properties of mortar with high contents of glass powder has not been carried out. For that, the main objective of this research is to conduct a detailed experimental study on the thermo-physical parameter variations (thermal conductivity, specific heat, thermal diffusivity, and thermal effusivity)
of the mortar as a function of the glass powder content (0 to 60%) in both dry and saturated states. The variation of these different parameters as a function of temperature was also considered. Physicochemical characterizations based on scanning electron microscopy and EDX analysis were made.

2. Materials and Methods

2.1. Materials

Glass bottles and recycled soda lime were collected from municipal landfills. They were then washed, crushed manually, and then finely crushed until the desired powder was obtained (Figure 1).

Figure 1. Glass powder preparation.

The Portland cement used is CPJ 45, containing a minimum clinker ratio of 65%, with the rest being made up of additions (fly ash and pozzolans).

This cement type is often appropriate for reinforced concrete, as well as for massive structures that require a moderate temperature rise. The crushing sand, coming from the Rabat–Sale region, was washed and then dried at 105 °C for 24 h. The particle size analysis of the two materials used (sand and glass powder) complies with standard NF P-18-560. Figure 2 represents the particle size analysis of the different materials used according to the NF P-18-560 standard.

Figure 2. Particle size distribution of glass powder and sand.

2.2. Samples Preparation

The samples were prepared in 40 mm × 70 mm × 90 mm containers. The cement was replaced by glass powder in different mass proportions: 10%, 20%, 30%, 40%, 50% and 60% (Figure 3). The control sample named MGP0 consists only of Portland cement CPJ45, sand, and mixing water.

The mortar samples studied were prepared with a first water/cement (W/C) ratio of 0.40 and a second Cement/Sand (C/S) ratio of 0.33.

The samples were removed from the molds and soaked in a water tank at 20 ± 1 °C for 28 days. Then, the samples were cured in a room conditioned at 20 ± 1°C for 91 days. After 91 days, each sample mortar’s dry state was obtained after drying the sample for
24 h in a cooker at 60 °C, while the saturated state was reached after soaking the sample in a tank of water for 48 h to ensure that the saturation point has been reached.

![Figure 3. Control mortar samples, substituted at different ratios of glass powder.](image)

The samples’ thermal properties were measured at the age of 91 days in both the dry and saturated state as a function of the temperature (20 °C, 30 °C, 40 °C and 50 °C).

2.3. Methods

The morphology of the samples was verified with a scanning electron microscope JEOL IT 100 type MEOL. In order to get the size of the particle down to four nm as a minimum, a thin layer of gold was used to make the surface more conducive. In order to determine the atomic composition of the samples used in this study, the scanning electron microscope was combined with an energy dispersive spectrometer, which also allows a microanalysis of the used samples in different states: powder or solid.

The thermal properties of the samples were measured using a “CT Meter” device (standard) delivered by the Modern Society of Electronic Studies. This device (CT Meter) measures both the thermal conductivity (W/(mK)) and the specific heat (KJ/m³K) of solid materials [18]. It is equipped with specific sonde for solid materials, a glove box and an interface that couples the editing with a computer to display and process the measured numerical values. The ring sonde is 60mm in width, 90 mm in length and 0.2 mm in thickness and contains a ring 10 mm in radius. The sonde was connected to the appliance (CT meter) via a plug (Figure 4). Then, it was inserted between two samples of the same size and shape so that it swept the sample in volume. The operator started the measurement by pressing the MEASURE button. From here, the cycle proceeded automatically, and at the end of the programmed measurement time, the display transmitted the results. Each measure is the average of three measures. Standard measurement uncertainty is 5%. The equipment used was developed by the CSTB (Technical and Scientific Center for Building) and it complies with the ASTM D5930-97 and AAC 11-3 RILEM recommendations [18].

![Figure 4. CT METER.](image)
The thermo-physical properties were determined at different temperatures using a hermetic glove box. It consists of a commercial freezer with a volume of 400 liters, internal dimensions of 120 cm length, 48 cm wideness and 72 cm height. The lid is made of transparent Plexiglas with a thickness of 20 mm. Inside the freezer, two ventilators are driven by 11 watt mini motors to agitate the air and homogenize its temperature. Depending on the desired heating power, one or two heating elements can be switched on at the same time. A contact thermometer controlled by a temperature controller is placed inside the box to keep the temperature stable. The measurement uncertainty of the thermo-regulated glove box is ±1 °C.

The thermal diffusivity (a) was estimated by the following equation:

\[ a = \frac{\lambda}{\rho c}, \]  

with \( a \): thermal diffusivity, \( \lambda \): thermal conductivity and \( \rho c \): volumetric specific heat.

3. Results and Discussions

3.1. Scanning Electron Microscopy (SEM) and Microanalysis by (EDX)

The SEM micrographs and the EDX analysis of the glass powder and the Portland cement samples were analyzed. In Figure 5a, the micrograph of the glass powder shows a sharp and varied smooth morphology, with a grain size ranging from 58 to 290 micrometer. However, as observed in Figure 5b, the Portland cement was constituted of finer regular spherical objects in the range of one micrometer. The results of the EDX microanalysis, presented in Table 1, show that the glass powder consists mainly of oxygen and silicon. We also observed a low content of calcium, carbon, sodium, and magnesium. However, cement is constituted by tricalcium silicate \((\text{Ca}_3\text{SiO}_5)\), dicalcium silicate \((\text{Ca}_2\text{SiO}_4)\), tricalcium aluminate \((\text{Ca}_3\text{Al}_2\text{O}_5)\), and calcium aluminoferrite \((\text{Ca}_4\text{Al}_n\text{Fe}_2\text{-nO}_7)\). The formula of these minerals can be broken down into basic calcium, silicon, aluminum, and iron oxides, with a strong dominance in calcium (the main component of limestone, which represents about 80% of raw materials in the Portland cement).

![Figure 5. Scanning electron microscopy of: (a) Glass Powder; (b) Cement.](image-url)

The microstructures of the mixtures of 0%, 10%, and 50% glass powder were also observed at their dry state using the SEM (Figure 6). The results of the EDX microanalysis are presented in Table 2. The chemical composition of the glass powder makes this material competitive as a pozzolanic material [24]. Thus, the pozzolanic reaction could densify the dough, thanks to the new C-S-H bonds. A weaker interaction of the Ca and Si elements of the alumina reveals that mixing with the glass powder will decrease the amount of portlandite and increase the amount of C-S-H. Figure 6a shows a dense structure of control mortar. The mixture with 10% of GP shows formations of gel C-S-H and secondary
hydration due to the pozzolanic characterization, as one can see in Figure 6b. However, this densification of the microstructure was not evident at 50% of the GP's Figure 6c. The difference in the pore size distribution can be observed for different substituents of the glass powder. We can state that the use of glass powder in the mortar leads to modifications of the pore size. According to Liu, Xie and Wang [29], the quantity of capillary pores decreases, while the quantity of the general porosity increases. This is due to the small size of the glass particles.

Table 1. Chemical composition of GP and Cement obtained from the EDX analysis.

| Formula | Glass powder (%atom) | Cement (%atom) |
|---------|----------------------|----------------|
| C       | 12.68                | 20.29          |

3.2. Thermo-Physical Properties

3.2.1. Relationship between Density and Thermal Conductivity

The density of the mortars’ glass powder (MGP) was measured at 20 °C for both dry and water saturated states. Each measure is the average of three measures. The diameter and height of each sample were measured with a digital caliper with a precision of 0.01 mm, while the mass was determined using a 0.005 g precision scale.

The results (Table 3) show that this density decreases in the dry state by a maximal percentage (about 11.16%) when the glass powder percentage is increased up to 60%. In the saturated state, the density decreases from 2.1 to 1.98 g/cm³ which corresponds to a variation of only 5.71%. This could be explained by the low absorption of water in the glass. The increase in the volumic mass of the samples in the saturated state compared to the dry state could be explained by water occupying the empty pores, which subsequently induces an increase of the density of the mortars.

Table 3. Measured densities of the mortar glass powder (MGP) samples in the dry and saturated states.

| MGP (%) | 0  | 10 | 20 | 30 | 40 | 50 | 60 |
|---------|----|----|----|----|----|----|----|
| Wet     | 2.1| 2.07| 2.05| 2.03| 2.01| 2.00| 1.98|
| Dry     | 2.06| 1.97| 1.95| 1.94| 1.90| 1.86| 1.83|

As shown in Figure 7, it can be noticed that the variation in thermal conductivity of the mortars incorporated by the glass powder linearly increases as their densities increase. This indicates the existence of a correlation between these thermophysical parameters. From the results shown in Figure 7, it is possible to establish a linear, empirical law between thermal conductivity and density in the case of mortars with different glass powder substitution rates. This result is similar to that obtained by [30], in which the thermal conductivity was strictly linked to the density of concrete. The increase in the substitution rate of the glass powder leads to an increase in the volume of the pores, which causes a lower density and consequently leads to a decrease of the thermal conductivity of the mortars.
3.2.2. Effect of Glass Powder Content on Thermal Conductivity and Specific Heat

Figure 8a illustrates the variation of the thermal conductivity as a function of the water content of the mortar at different percentages of glass powder. This curve clearly shows that the thermal conductivity and the specific heat decrease with the addition of glass powder. This thermal conductivity decreases up to 0.86 W/(mK) when the percentage of glass powder reaches 60%, which corresponds to a reduction of 37.32% when compared to the control mortar. These results are in agreement with those of [31], who showed that the thermal conductivity of the cement paste decreases with the addition of glass powder and for glass substitution rates lower than 20%. We attribute this decrease in thermal conductivity based on the substitution rate to the fact that the glass is amorphous and non-conductive. The presence of air (0.03 W/(mK)) in the porous material can also significantly influence thermal conductivity.

However, samples saturated with water have a higher thermal conductivity. This can be explained by an increase in the pores accessible to water, which has a thermal conductivity (0.59 W/(mK)) greater than that of air at room temperature.

Measurements of the specific heat of the mortars were carried out for different substitution rates for glass powder in dry and saturated states using a CT meter machine. These results (Figure 8b) show that in the dry state, the specific heat of mortars decreases from 2155 to 1757 KJ/m^3K when the glass substitution rate varies from 0 to 60%, i.e., a variation...
of 18.46%. This result is in complete agreement with the work of Pan et al. [20]. The resulting material is characterized by new thermo-physical properties. These properties are attributed to exothermic hydration reactions, which are activated when the binder is mixed with water. The localized heat released will reorganize the water molecules in the microstructure of the skeleton. Unlike thermal conductivity, specific heat does not depend on how its different constituents are arranged but on the volume fraction of its components. The small decrease in the specific heat of the mortars as a function of the glass powder percentages is explained by the low specific thermal value of the glass (913 KJ/m$^3$K) and that of the air (1005 KJ/m$^3$K) which are located in pores.

In the saturated state, the specific heat decreases from 2325 to 1979 KJ/m$^3$K, a variation of 14.88%. The increase in specific heat from dry to saturated state is due to the increase in the amount of water absorbed in the pores and, therefore, to the replacement of air, which has low specific heat, by water (4181.3 KJ/m$^3$K).

3.2.3. Effect of Glass Powder Content on Thermal Diffusivity

Thermal diffusivity is the quotient of thermal conductivity over specific heat. The results represented in Figure 9 have been deduced from the Equation (1).

![Figure 9. Variation of the measured thermal diffusivity at dry and wet states as a function of the glass powder content.](image)

The curve in Figure 9 shows that the thermal diffusivity decreases, in the dry state, from 0.63 to 0.49, which corresponds to an average of 22.22%. However, in the saturated state, this thermal diffusivity decreases from 0.69 to 0.64, which corresponds to an average of 7.24%. This new result is in full agreement with the previous results, in which we have shown a decrease in both thermal conductivity and density as a function of the glass powder content, which is also associated with a small decrease in specific heat. In the following sections, we will present the behavior of the thermal diffusivity of mortars with the glass powder content.

3.3. Influence of Temperature on Thermal Conductivity and Specific Heat

Temperature is a factor that influences the thermal properties of concrete and mortar. The study of the thermal properties of glass-based mortars, at high temperatures, has been the subject of this research study [20]. Until now, the study of the thermal properties of substituted mortars with a high content of glass powder as a function of temperature, while very important, has not yet been carried out. For this, we present here a detailed study of the influence of temperature on the thermal properties of mortars based on glass with different contents (10%, 20%, 30%, 40%, 50% and 60%). The thermal properties of carefully prepared mortars were measured in the dry state, in a temperature range between 20 and 50 °C, using the CT meter instrument equipped with a temperature regulator. The results
obtained, presented in Figure 10a, show that the thermal conductivity undergoes a strong decrease if the rate of substitution in glass powders increases. This tendency remains valid for all the temperatures studied (between 20 and 50 °C). However, these results also show, as expected, a decrease in thermal conductivity if the temperature decreases. The thermal conductivity goes from 1.11 to 0.86 W/(mK) for the mortar at 60% glass powder when the temperature is set at 20 °C. There is also a remarkable slowdown in the rate of growth of thermal conductivity above 40 °C. The linear tendencies of the thermal conductivity curves proves that it is possible to establish a simple empirical law allowing expression of the variation of thermal conductivity as a function of the temperature and the glass powder content.

It is interesting to note that the samples are composed of solid (mineral), liquid (water), and gas (air) phases. The thermal conductivity of several minerals (amorphous quartz, etc.), which make up the mortar, increases with temperature. Even if the samples have been oven-dried, there may still be water or gas trapped in the pores. However, the thermal conductivity values of air and water in the temperature range (20–50 °C) are respectively (0.026–0.028 W/(mK)) and (0.59–0.64 W/(mK)). These observations may partly explain the remarkable slowing down of the growth rate of thermal conductivity above 40 °C, illustrated in Figure 10a. This result can also be explained in part by the fact that an increase in temperature causes an expansion of the grains and, therefore, a decrease in porosity. Thus, the heat flow then passes through the particles of glass, sand, and cement. Figure 10a clearly shows that at a fixed temperature, the thermal conductivity of mortars decreases if the percentage of glass powder substitution increases. This is due to the fact that glass powder, having a thermal conductivity of 0.18 W/(mK), constitutes a good thermal insulator. Specific heat is a thermodynamic variable, which varies as a function of temperature. The results presented in Figure 10b show that the specific heat increases if the temperature increases and/or the substitution rate decreases. The specific heat of the control mortar increases from 2155 to 2434 KJ/m³K, and the mortar with a high glass powder content (60%) increases from 1757 to 2170 KJ/m³K between 20 and 50 °C. The specific heat of the different types of light aggregate concrete studied decreases to a minimum value when the temperature is between 5 and 20 °C, then increases with increasing temperature at 50 °C, which is similar to the results obtained for mortars with different substitutions of glass powder.
4. Conclusions

The aim of this study is to evaluate the influence of soda-lime glass waste, as a cement substitute, on the thermophysical properties of cement mortar.

The following major conclusions can be drawn:

- The incorporation of waste glass powder contents into the cement mortar reduced the thermophysical properties’ values by 37, 18 and 22% respectively for thermal conductivity, volumetric specific heat and thermal diffusivity. In a dry state, the increase in the substitution rate of the glass powder leads to an increase in the volume of the pores, which causes a lower density and consequently, the thermal conductivity and volumetric specific heat of the mortars decreases. This could be explained by the low absorption of water in the glass. In a saturated state, the increase in the volumic mass of the samples could be explained by water occupying the empty pores, which subsequently induces the increase of the density of the mortars.

- According to SEM results, the chemical composition of the glass powder makes this material competitive as a pozzolanic material. The glass powder addition decreases the portlandite quantity and develops C-S-H gels. The use of glass powder in the mortar leads to modifications of the pore size.

- The density of the new mortar was also reduced by approximately 11% in the dry state and 5% in the wet state. This decrease in density, dry and/or wet, has a significant effect on the thermo-physical parameters of this composite compared to the reference mortar.

- Incorporation glass powder also reduces the specific heat for the two hydric states discussed (dry and saturated). This can be explained by the low specific thermal value of the glass (913 KJ/m$^3$K), which is located in pores.

- The thermal conductivity increases when the temperature increases and/or the substitution rate decreases. Thus, at 60% glass powder, the thermal conductivity increases by 22.25% when the temperature varies from 20°C to 50°C. This result can be explained in part by the fact that an increase in temperature causes an expansion of the grains and, therefore, a decrease in porosity.
