Abstract: The purpose of this study is to assess the integrity of carbon-fibre reinforced plastics (CFRP) comprising of commercial and surface modified CFs through nanomechanical mapping protocol, towards the feasibility of nanoindentation tool as a quality assurance means in a composite manufacturing process. Carbon fibre surface modification was selected for enhancement of the wetting properties of carbon fibres in order to improve the adhesion force between the fibre and the polymer matrix. In all cases, epoxy resin was used as a matrix for the manufacturing of composite samples. Plastic deformation/elastic recovery were recorded (together with viscoelasticity and adhesion-discontinuities and fluctuations during measurement), while elastic modulus values are also mapped. Moreover, the resistance to applied load is assessed and compared for all cases.

Keywords: nanoindentation; mapping; carbon; fibre; composite; integrity

1. Introduction

Recently carbon fibres (CFs) has been placed among reinforcement filler candidates with potential, whereas epoxy-based matrices (e.g., thermoplastic polymers) are basically addressed for the manufacturing of composites, meeting a plethora of application target needs, i.e., from automotive to aeronautics, health, and structural/building constructions and processes. Carbon fibre composites reveal increased enhanced mechanical performance, significantly high strength and modulus, increased resistance to creep deformation and stiffness [1,2], to name a few; yet, as fibre-matrix strong chemical bonding is rather scarce, under stress loading [3], the CF composite exhibit decreased mechanical properties, e.g., poor interlaminar shear strength (ILSS) and toughness, as stress propagates from one filament to others, occurring through the matrix resin [3]; consequently, pull-out effect occurs, confronted through various approaches of treating the surface in order to incorporate active groups onto fibres surface, resulting in enhancement of CF-matrix. However, if the bond strength is high brittle behaviour occurs, whereas if this incorporation is feeble it leads to failure [3,4].

Various surface treatments have been investigated [5,6]; its impact assessment consists of sizing and heat treatment assessment on physicochemical properties as well as electrolysis of anodic oxidation. Chemically treating the surface is also of major importance for the development of CF-matrix interface enhancement and tailoring its properties [7,8].

Totally novel approaches for instrument design and experimental protocols based on a combination of expertise and innovation help to meet current instrumentation requirements for quality assurance, needed accuracy and measurement speed for e.g., additive manufacturing (AM) operations [9]. Nanoindentation technique is now considered as a credible and rapid assessment for
the mapping of localized surface mechanical integrity [10,11]; via this, a diamond indenter of specific
design and geometrical dimensions is driven into a specimen surface, while the applied force and
the displacement values are correlated simultaneously and loop-controlled through actuators and
sensors [12]. The hardness (as contact pressure, in the means of resistance to applied load) and the
elastic modulus of the material being probed are calculated from the initial part of the unloading
curve, on the assumption of elastic behaviour using the theory of contact mechanics [13]. Information
on the elastic recovery and plastic deformation [14] is also provided, fracture [15], sensitivity of
strain-rate and strain-hardening, residual stresses effect [16], and size effects in plasticity locally [17].
As nanoindentation is being recently utilised for assessing the in situ properties of fibrous composite
constituents [18,19], issues such as effects of sample preparation, neighbouring constituents, residual
stress, pile-up, time-dependent deformation and hydrostatic stress on the important nanoindentation
parameters and properties need to be carefully considered [20]. However, since manufacturing
and industrial applications needs for quick in-line and real-time testing emerge, the feasibility of
nanomechanical assessment and rapid mechanical response mapping over large areas in composites
and hybrids arises [12,21,22].

2. Experimental

2.1. Materials

Carbon fibres were purchased from Toray Industries Inc. (Tokyo, Japan). Epoxy resin Araldite
GY 257 (Jubail Chemical Industries, JANA, Kingdom of Saudi Arabia), 2,2’-diaminodiethylamine
(HY 943, Sigma-Aldrich, St. Louis, MO, USA) and N,N-methylenebis(acrylamide) (Acros Organics,
Morris Plains, NJ, USA) were utilised as received. Double distillation occurred to acrylic acid (Acros
Organics, Morris Plains, NJ, USA), methacrylic acid (Acros Organics, Morris Plains, NJ, USA),
acrylonitrile (Acros Organics, Morris Plains, NJ, USA), and N-vinylpyrrolidone (Acros Organics,
Morris Plains, NJ, USA), under reduced pressure prior to use. The surface of commercial carbon
fibres was functionalized through cyclic voltammetry in aqueous electrolyte solutions of H₂SO₄, in the
presence of acrylic acid, methacrylic acid, acrylonitrile, and N-vinylpyrrolidone monomers, resulting
in four types of electropolymerized CF samples, namely with acrylic acid (PAA), methacrylic acid
(PMAA), acrylonitrile (PAN), and N-vinylpyrrolidone (PVP). The specifications of the obtained CFs
and epoxy resin are reported in the authors’ previous work [1].

2.2. Characterisation Methods

Indentation data provide significant information under localised compressive loading; for carbon
nanotube forest use, e.g., as super-compressive cushions, electrical contacts and switches, or thermal
conduits, knowing the applied displacements is necessary to identify the extent of the buckling
region which acts to provide energy absorption [13]. The nanoindentation tests were performed
using a Hysitron (Minneapolis, MN, USA) TriboLab® Nanomechanical Test Instrument equipped
with a Berkovich diamond indenter (average radius 100 nm) which allows the application of loads
from 1 to 30,000 µN and records the displacement as a function of applied loads with a high load
resolution (1 nN) and a high displacement resolution (0.04 nm). Details about the instrument and
the experimental setup have been presented elsewhere [23]. Prior to indentation, the area function
of the indenter tip was calibrated in a fused silica and in a soft PS-6 sheet (Eₘ = 0.007 GPa (7 MPa))
for shallow depths, standard materials for this purpose. All nanoindentation tests were conducted
in a clean area environment with 45% humidity and 23 °C ambient temperature with displacement
feedback control closed loop [23]. Samples of ~55% volume fraction were carefully prepared so as to
have ~1.2 µm from the upper fibres to the sample surface; indenter was selected to probe at 200 nm
displacement (below 10% of empirical rule-of-thumb, [24,25]), in order for the obtained values to
represent the system matrix fibre in each case. In this way, the indentation occurs at epoxy surface
(matrix) (Figure 1), while the affection of the fibres (and thus their interface) underneath is revealed through variation in resistance to applied load and load-unload curve form [26].

Figure 1. SEM images of carbon fibres, reproduced from [1].

2.3. Surface Treatment, Composite Manufacturing and Assessment

All electropolymerization experiments were performed at room temperature, in one-compartment electrochemical cell of 150 mL volume consisting of CF as a working electrode (≈1.0 cm² of exposed area), a saturated silver chloride electrode (Ag/AgCl, KCl(sat)) as a reference and a platinum foil as a counter electrode. Details about the process can be found elsewhere [1]. Carbon fibre bundles (pristine and modified) were placed inside dumb bell type sacrificial templates and then the epoxy resin solution was added to each template (dimensions according to ASTM D638-14). The synthetic process for the epoxy resin solution was followed according to our previous work [27]. The wt% material concentration of the epoxy solution is tabulated in Table 1.

Table 1. Concentration details for the preparation of the epoxy solution.

| Reagent   | GY 257 | HY 943 | Acetone |
|-----------|--------|--------|---------|
| Wt%       | 20.0   | 1.76   | 76.48   |

In the authors’ previous work [1], Raman and FTIR (Fourier transformed infrared) spectroscopic techniques have revealed the characteristic bands of commercial sizing and polymer surface modification; moreover all the modified fibres demonstrated higher values of ratio ID/IG compared to the value of pristine fibres, indicating an increase of the defects of the graphitic lattices due to the grafting of the corresponding polymers (ratio ID/IG is an important factor to evaluate the fibre microstructure heterogeneity and increases when a reduction of the crystallite sizes exists) [1]; scanning electron microscopy (SEM) images are presented in Figure 1. Through tensile testing, all polymer-modified carbon fibre composites exhibited increased ultimate tensile strength compared to the pristine, with the PAA-modified specimen revealing higher elongation, probably due to higher polymer weight gain compared to the other specimens.
3. Results and Discussion

Load-depth response measurements of the carbon-fibre reinforced plastics (CFRP’s) were performed [13]. In Figure 2, the schematic protocol is depicted; the indenter probes the material in a square mapping grid [21,23] of 64 indents (selected area of 45 × 45 µm², 5 µm distances between indents).

**Figure 2.** Nanoindentation schematic representation of mapping grid measurements (a); the indentation occurs at epoxy surface (matrix) (b), while the affection of the fibres (and, thus, their interface) underneath is revealed through the variation in resistance to an applied load and load-unload curve form.

In Figures 3–6, load-displacement data from the loading-unloading cycles at 200 nm of displacement, for all samples, are presented. The plasticity index (plastic deformation, reverse to elastic recovery) [15] for nanoindentation is calculated as the ratio of the total integrated area of displacement, for the epoxy-CF plain sample.

**Figure 3.** Load-displacement data from the loading-unloading mapping measurements at 200 nm of displacement, for the epoxy-CF plain sample.
Figure 4. Load-displacement data from the loading-unloading mapping measurements at 200 nm of displacement, for the epoxy-PAACFs sample.

Figure 5. Load-displacement data from the loading-unloading mapping measurements at 200 nm of displacement, for the epoxy-PANCFs sample.

Apparently, there is a need for taking into consideration the possibility of creep affecting the results when experimental nanoindentation data are to be re-used to calculate constitutive relations. Figure 4 depicts the loading–unloading data for epoxy-PAACFs samples, which shows interesting local discontinuities [20–25] measured in the load-controlled loop test of this study; these are evidence of energy-absorbing/energy-releasing events occurring below Berkovich indenter. The transition from
purely elastic to elastic/plastic deformation [20,24], occurring as a gradual slope change (yield-type “pop-in”), is depicted for epoxy-PANCFs at 20 nm of displacement. As nanoindentation technique is performed locally, an increase in local crystallinity may also result in a modulus values increase. In Figure 7, elastic deformation (recovery, as dissipated energy [15]) obtained from mapping data at 200 nm of displacement, for (a) epoxy-CFs (benchmark), (b) epoxy-PAACF (low resistance to applied load) and (c) epoxy-PMAACFs samples (high resistance to applied load), are presented. epoxy-CFs sample exhibits the highest elastic recovery; epoxy-PAACFs sample exhibits the lowest elastic recovery, while the epoxy-PMAACFs sample exhibits the highest elastic recovery, compared with epoxy-PANCF and epoxy-PAACF samples.

Figure 6. Load-displacement data from the loading-unloading mapping measurements at 200 nm of displacement, for the epoxy-PMAACFs sample.

Figure 7. Cont.
Figure 7. Elastic deformation (recovery) obtained from the loading-unloading mapping measurements at 200 nm of displacement, for (a) epoxy-CFs (benchmark), (b) epoxy-PAACF (low resistance to applied load), and (c) epoxy-PMAACFs samples (high resistance to applied load).

Elastic modulus (values referring to epoxy, affected by extent of interfacial adhesion and, thus, overall CFRP integrity) mapping for all samples showed that for the case of epoxy-PMAACFs, higher values (~3.5 GPa) are evidenced; this is also consistent with values from Figure 6, as it is denoted that higher applied loads are required for reaching 200 nm of displacement, comparing this with all other samples (of which the max. modulus values reached ~1.7 GPa). In Figures 8–11, elastic modulus obtained from nanoindentation mapping measurements at 200 nm of displacement for all samples are presented. The 64 points are presented in red dots (base, X–Y axes), while elastic modulus values are presented in black; through trajection (blue colour), the deviation range of elastic moduli is depicted. epoxy-PMAACFs sample exhibits the highest elastic moduli range (up to ~3.4 GPa), while rest of the samples exhibit elastic moduli range up to ~1.7 GPa.
Figure 8. Elastic modulus obtained from the loading-unloading mapping measurements at 200 nm of displacement for the epoxy-CFs sample.

Value increases represent the fibres underneath the indenter, while value decreases represent the area in between fibres.
4. Conclusions

The purpose of this study was to assess the integrity of CFRP comprising of commercial and surface modified CFs through a nanomechanical mapping protocol, towards the feasibility of a nanoindentation tool as a quality assurance means in a composite manufacturing process. The obtained results reveal that, for the case of epoxy-PAACFs, an increased plastic deformation is recorded (together with viscoelasticity and adhesion-discontinuities, and fluctuations during measurement), while the epoxy-PMAACF sample exhibits the highest elastic recovery, compared with epoxy-PANCF and epoxy-PAACF samples. Elastic modulus (values referring to epoxy, affected by extent of interfacial adhesion and, thus, overall CFRP integrity) mapping for all samples at 200 nm of displacement revealed that for the case of epoxy-PMAACFs, increased values are recorded. As for resistance to applied load, epoxy-PANCF and epoxy-PAACF samples exhibit lower resistance to applied load compared with epoxy-PMAACFs. Overall, epoxy-PMAACFs comprise the most suitable CF surface modification, with decreased plastic deformation and increased elastic modulus, while the resistance to applied load of the points that correspond to measurement on top of fibre upper area are higher from those of epoxy-CFs (benchmark). Additionally, identification of fibre orientation through elastic modulus nanoindentation mapping measurements at 200 nm of displacement for the epoxy-PMAACFs sample was achieved.

To conclude, a grid mapping protocol was proved as a powerful tool for the integrity assessment of CFRPs through nanomechanical mapping, revealing the effect extent of CF surface modification and selecting the appropriate CF surface modification.
