Keywords: Brownian Motion, Relativistic Langevin simulation, Boltzmann-Jüttner distribution, Heavy-quark diffusion

PACS numbers: 12.38.Mh, 05.10.Gg, 25.75.-q

I. INTRODUCTION

Since its introduction more than 100 years ago, Brownian motion has remained a valuable and versatile tool to study a wide variety of physical systems. In recent years considerable efforts have been devoted to its extension and reliable implementation for relativistic systems [1–5]. In particular, it has been applied in the studies of heavy-quark diffusion in the Quark-Gluon Plasma (QGP) [6–10], in order to evaluate transport properties of the medium produced in ultrarelativistic heavy-ion collisions (URHICs) (see, e.g., Ref. [11] for a recent review). Since charm- and bottom-quark masses are much larger than the typical temperatures, as well as the constituent masses of the equilibrium medium, a separation of the relaxation time and collision time emerges [6–11], thus justifying a soft-collision approximation to be accommodated by Fokker-Planck dynamics [12]. In practice, the Fokker-Planck equation is routinely realized by stochastic Langevin processes [2, 3, 11, 13]. However, it is known that the implementation of the Langevin equation is not unique but depends on the realization of the stochastic integral, resulting in (seemingly) different Fokker-Planck equations, known as the “Ito-Stratonovich dilemma” [2, 3, 13]. Moreover, the ambiguities in the Langevin discretization scheme raise concerns on the asymptotic phase-space distribution of the relativistic Brownian particles under consideration. The latter has been an issue of debate (see Ref. [13] and references therein) but should be constrained by the long-time limit of equilibrium [2, 12, 13, 22], i.e., by a “detailed-balancing” of the drag and diffusion terms of the underlying Fokker-Planck equation.

The large collective flow of the medium created in URHICs (reaching collective velocities in excess of half the speed of light), and in particular subtle angular modulations thereof (such as the elliptic flow), make a good understanding of differences in the realization of relativistic Langevin simulations mandatory. In particular, the description of the phase-space distribution of a Brownian particle (the heavy quark), which is usually formulated in laboratory-frame coordinates, needs to manifestly recover the equilibrium limit given by the Lorentz-invariant Boltzmann-Jüttner distribution [18, 19]. This is evident as the underlying Fokker-Planck equation is to yield a good approximation of the Lorentz-covariant Boltzmann equation [1, 12, 13]. This problem has been addressed, e.g., in Refs. [13, 23] within the so-called Ito realization, while pertinent Fokker-Planck equations following from different Langevin prescriptions have been given in Ref. [13]. More recently, a Lorentz-covariant implementation of the Langevin process has been discussed in Ref. [24] based on a relativistic fluctuation-dissipation theorem.

In the present work we pursue a slightly different approach. We start from a Fokker-Planck equation with transport coefficients obtained from an underlying microscopic theory, in the sense of an approximate treatment of the collision integral in the transport equation. After recovering the generalized relativistic Einstein relation for these coefficients, we discuss their implementation into different Langevin realizations and verify their uniqueness in explicit examples, in particular including the case of expanding media. We also show how vari-
ations in the Langevin coefficients induce modifications to the long-time limit (equilibrium) distribution of the Brownian particle. For definiteness, our numerical applications will be illustrated in the context of HQ diffusion in an expanding QGP as formed in URHICs.

Our article is organized as follows. In Sec. II we introduce the Fokker-Planck equation as an approximate description of the Boltzmann equation, and recall the general equilibrium condition constraining its drag and diffusion coefficients. In Sec. III we elaborate how Langevin prescriptions emerge from the pertinent equilibrium conditions to ensure a uniform outcome of the Fokker-Planck framework, i.e., how Fokker-Planck equations resulting from different Langevin prescriptions take the same form as for the medium constituents given by the relativistic Boltzmann-Jüttner distribution [12], the Boltzmann integro-differential equation describing the motion of the heavy particles in an equilibrated background medium reduces to the Fokker-Planck equation for the phase-space distribution function, \( f \), of the “Brownian” particle [12]

\[
\frac{\partial f(t, p)}{\partial t} = \frac{\partial}{\partial p_i} \left\{ A_i(p) f(t, p) + \frac{\partial}{\partial p_j} [B_{ij}(p)f(t, p)] \right\}
\]  

(1)

with \( i, j \in \{1, 2, 3\} \). We focus on a spatially homogeneous static medium without external force, and thus the phase-space density is independent of \( x \). The drag and diffusion coefficients in Eq. (1), \( A_i(p) \) and \( B_{ij}(p) \), respectively, are obtained from an average of the moments of momentum transfer in heavy-light collisions, weighted by a transition probability given by the pertinent scattering matrix elements, \( \mathcal{M} \), and the medium particle distribution, \( f^\pi \),

\[
A_i(p) = \frac{1}{2E(p)} \int \frac{d^3q}{(2\pi)^32E(q)} \frac{d^3q'}{(2\pi)^32E(q')} \times \int \frac{d^3p'}{(2\pi)^32E(p')} 1 \sum |\mathcal{M}|^2 \hat{f}(q') (2\pi)^3\delta^4(p + q - p' - q') [(p' - p)_i]
\]

(2)

\[
B_{ij}(p) = \frac{1}{2} \langle \langle (p' - p)_i(p' - p)_j \rangle \rangle.
\]  

(3)

Here, \( p \) and \( p' \) (\( q \) and \( q' \)) are the heavy (light) particle’s momentum before and after the collision, respectively, and \( \hat{f} = f^\pi (1 \pm f^\pi) \) for bosons/fermions in the medium.

Defining a current

\[
S_i(t, p) = - \left\{ A_i(p) f(t, p) + \frac{\partial}{\partial p_j} [B_{ij}(p)f(t, p)] \right\},
\]  

(4)

the Fokker-Planck equation can be cast as a continuity equation in momentum space [12],

\[
\frac{\partial f(p, t)}{\partial t} + \frac{\partial}{\partial p_i} S_i(t, p) = 0.
\]  

(5)

This identifies \( S_i \) as a particle-number current (flux), so that the number of heavy particles is conserved in the diffusion process. After sufficiently many collisions with the light partons, i.e., in the long-time limit, we expect the heavy particle to approach the same equilibrium distribution as for the medium constituents given by the relativistic Boltzmann-Jüttner distribution [20],

\[
N_{eq}(p, T) = N \exp[-E(p)/T],
\]  

(6)

where

\[
\sqrt{p^2 + m^2} \quad \text{is the relativistic on-shell energy of the Brownian particle and T the temperature of the equilibrated medium.}
\]

In addition, in statistical equilibrium, the particle flux has to vanish [12]: \( S_i(p) = 0 \). Together with the Boltzmann-Jüttner distribution [9] this yields a dissipation-fluctuation relation between drag and diffusion coefficient,

\[
A_i(p, T) = B_{ij}(p, T) \frac{1}{T} \frac{\partial E(p)}{\partial p_j} - \frac{\partial B_{ij}(p, T)}{\partial p_j}.
\]  

(7)

This is the manifestation of the detailed-balance property of the collision-transition probabilities, which is due to the unitarity of the S-matrix of quantum-field theory and thus embodied in the collision integral of the underlying full Boltzmann equation [12]. This relation is not a priori fulfilled by Eqs. (2) and (4), and may suffer in accuracy if the assumption of a forward-peaked transition-matrix element is not well satisfied. In order for the heavy particle to approach the same distribution as for the medium particles, the drag and diffusion coefficients are not independent but have to be related to each other precisely as specified by the dissipation-fluctuation relation (7). This general equilibrium condition plays a central role in the following discussions.
III. STOCHASTIC LANGEVIN REALIZATION OF FOKKER-PLANCK DIFFUSION

A. Langevin Simulation

The Fokker-Planck description of diffusion can be realized by Langevin’s stochastic differential equation(s) \[11, 13\]. Employing a spatially homogeneous static medium, we follow the notation in Ref. \[11\] to write the Langevin equations as

\[
\begin{align*}
\dot{x}_j &= \frac{p_j}{E} dt, \\
\dot{p}_j &= -\Gamma(p,T) p_j dt + \sqrt{d} C_{jk}(p + \xi dp, T) \rho_k,
\end{align*}
\]

which specify the rules for updating the coordinate and momentum of the heavy particle in time steps, \(dt\). In Eq. \(9\), \(\Gamma(p,T)p\) is the deterministic friction force, whereas the \(C_{jk}\) describe the stochastically fluctuating force with independent Gaussian noises \(\rho_k\) following a normal distribution, \(P(\rho) = (2\pi)^{-3/2}e^{-\rho^2/2}\). Thus, there is no correlation in the stochastic forces at different times, \(\langle F_j(t)F_k(t') \rangle = C_{jk}(t\delta(t-t'))\), consistent with the assumption of uncorrelated momentum kicks underlying the Fokker-Planck equation (“white noise”). However, it is not specified at what momentum argument the covariance matrix should be evaluated: \(C_{jk} = C_{jk}(t, p + \xi dp)\), with \(\xi \in [0,1]\), e.g., \(\xi = 0\) for pre-point (Ito) \[21\], \(\xi = 1/2\) for mid-point (Stratonovich), or \(\xi = 1\) for post-point (Hänggi-Klimontovich) \[2\] realizations of the stochastic integral. We will return to this point below.

The phase-space distribution determined by the Langevin equations \[8\] and \[9\] satisfies a Fokker-Planck equation, which can be found by calculating the average change of an arbitrary phase-space function with time \[11\]. The resulting equation reads

\[
\frac{\partial f(t,p)}{\partial t} = \frac{\partial}{\partial p_j} \left[ \left( \Gamma(p)p_j - \xi C_{ik}(p) \frac{\partial C_{jk}(p)}{\partial p_l} \right) f(t,p) \right] + \frac{1}{2} \frac{\partial^2}{\partial p_j \partial p_k} \left[ C_{jl}(p) C_{kl}(p) f(t,p) \right].
\]

Comparing Eqs. \[10\] and \[11\] leads to

\[
\begin{align*}
A_j(p) &= A(p)p_j - \xi C_{ik}(p) \frac{\partial C_{jk}(p)}{\partial p_l}, \\
B_{jk}(p) &= B_0(p) P_{jk}^\perp(p) + B_1(p) P_{jk}^\parallel(p) \\
&= \frac{1}{2} C_{jl}(p) C_{kl}(p),
\end{align*}
\]

where \(P_{jk}^\perp(p) = \delta_{jk} - p_j p_k/p^2\) and \(P_{jk}^\parallel(p) = p_j p_k/p^2\) are the corresponding projection operators, so that

\[
C_{jk}(p) = \sqrt{2B_0(p)} P_{jk}^\perp(p) + \sqrt{2B_1(p)} P_{jk}^\parallel(p).
\]

Two comments are in order here. First, note that the friction coefficient, \(\Gamma(p,T)\), appearing in the Langevin equation \[9\], is a derived quantity, given in terms of the drag and diffusion coefficients, \(A(p,T), B_0(p,T)\) and \(B_1(p,T)\), as determined by microscopic scattering-transition matrix elements (e.g., they relate to heavy-quark energy loss due to elastic heavy-light collisions \[28\]). Second, the Fokker-Planck equation and the Langevin equation are specified for a spatially homogeneous static medium; neither of them is manifestly Lorentz covariant. Thus, in the case of a flowing medium, momentum updates in the Langevin equation \[9\] have to be calculated in the local fluid-rest frame and then boosted back to the moving frame when performing the diffusion simulations. It is readily proved that the coordinate updates \[8\] can be equivalently done in the moving frame; hereafter, we refer to the latter as the laboratory frame.

B. Evaluation of Equilibrium Condition

We now proceed to analyze the equilibrium condition for two implementations of the Langevin process, the pre- and post-point prescriptions, and work out their manifestations in the Fokker-Planck framework. For the sake of brevity, but without loss of generality, we work with a diagonal approximation of the diffusion coefficient from here on. Putting \(B_0(p) = B_1(p) = D(p)\), the covariance matrix \[13\] reduces to \(C_{jk}(p) = \sqrt{2D(p)} \delta_{jk}\). Utilizing Eq. \[11\], the general equilibrium condition \[7\] simplifies to

\[
A(p) = \frac{1}{E(p)} \left( D|E(p)|/T - \partial D/E(p) \right)
\]

with

\[
\Gamma(p) = \frac{1}{E(p)} \left( D|E(p)|/T - (1 - \xi) \partial D/E(p) \right).
\]

Thus, for a given drag coefficient \(A\), Eq. \[14\] should be solved to obtain the diffusion coefficient \(D\), which can then be used to deduce the friction force \(\Gamma\) from Eq. \[15\]. Alternative procedures have been adopted in the literature by, e.g., calculating \(D\) and adjusting \(A\) \[5, 23\]. Condition \[15\] has also been derived as the generalization of the fluctuation-dissipation theorem with Boltzmann-Jüttner distributions as the equilibrium solution in \[24\].

In the non-relativistic limit, both \(D(p) = D\) and \(\Gamma(p) = \gamma\) become independent of \(p\), and \(E(p) \to m\); the equilibrium condition reduces to

\[
D = m \gamma T,
\]

which is Einstein’s classical fluctuation-dissipation relation \[12\].

In terms of the diagonal diffusion coefficient, the Langevin updating rules now read

\[
\begin{align*}
\dot{x}_j &= \frac{p_j}{E} dt, \\
\dot{p}_j &= -\Gamma(p)p_j dt + \sqrt{2dt D(p + \xi dp)} \times \rho_j.
\end{align*}
\]
In the following, we discuss their explicit forms in the pre-
point and post-point Langevin prescriptions as following 
from the corresponding equilibrium condition, and show 
that they can both be rendered compatible for a given 
microscopic model.

1. Pre-point scheme: $\xi = 0$

In this scheme, the equilibrium conditions (14) and (15) read

$$\Gamma(p) = \frac{1}{E(p)} \left( \frac{D[E(p)]}{T} - \frac{\partial D[E(p)]}{\partial E} \right) = A(p) .$$  \hfill (19)

Note that the friction force entering the Langevin equa-
tion is equal to the drag coefficient defined by Eq. (2).

Inserting $C_{jk}(p) = \sqrt{2D(p)}d_{jk}$ into Eq. (10), the 
Fokker-Planck equation realized in the pre-point 
Langevin scheme takes the form

$$\frac{\partial}{\partial t} f(t, \mathbf{p}) = \frac{\partial}{\partial p_i} \left\{ \Gamma(p) p_i f(t, \mathbf{p}) + \frac{\partial}{\partial p_i} [D(p)f(t, \mathbf{p})] \right\} .$$  \hfill (20)

The corresponding Langevin updating rules now read

$$\begin{align*}
dx_j &= \frac{p_j}{E} \, dt , \\
dp_j &= -\Gamma(p)p_j \, dt + \sqrt{2dtD(p)} \rho_j ,
\end{align*}$$  \hfill (21, 22)

where carrying out the Langevin time steps is straightfor-
ward: starting with initial coordinate $x$ and momentum $\mathbf{p}$ of a test particle, calculate the coordinate increment $dx_j$ within the time step $dt$ using Eq. (21); at the same 
time substitute the drag coefficient $A(p) (= \Gamma(p))$ 
evaluated at $p = |\mathbf{p}|$ and the corresponding $D(p)$ calculated 
from Eq. (14) into Eq. (22) to calculate the momentum increment. Then go to the next time-step with (new) initial coordinate $x + dx$ and momentum $\mathbf{p} + dp$.

2. Post-point scheme: $\xi = 1$

In this scheme, the equilibrium conditions read

$$D[E(p)] = \Gamma(p)E(p)T ,$$  \hfill (23)

$$\Gamma(p) = A(p) + \frac{1}{E(p)} \frac{\partial D[E(p)]}{\partial E} .$$  \hfill (24)

Here, the scheme-dependent relation takes a simple form, 
but the “price” to pay is that the friction force $\Gamma(p)$ 
figuring into the Langevin equation is different from the drag 
coefficient $A(p)$. In this sense, starting from a micro-
scopic model for $A(p)$, there is no difference in the choice 
of the pre-point or the post-point scheme.

The corresponding Fokker-Planck equation in the post-
point scheme takes the form

$$\frac{\partial}{\partial t} f(t, \mathbf{p}) = \frac{\partial}{\partial p_i} \left\{ \Gamma(p)p_i f(t, \mathbf{p}) + D(p) \frac{\partial}{\partial p_i} f(t, \mathbf{p}) \right\} .$$  \hfill (25)

This Fokker-Planck equation appears to be different 
from its counterpart realized in the pre-point realiza-
tion, Eq. (20). However, upon substituting the differ-
ent expressions for $\Gamma$, Eqs. (19) and (21), for the pre-
point and the post-point Langevin scheme into Eqs. (20) 
and (25), respectively, one immediately sees that the 
Fokker-Planck equations realized in the pre- and post-
point Langevin schemes are actually the same in terms 
of $A(p)$ and $D(p)$. This is a desired result since the (ap-
proximate) realization of the underlying full Boltzmann 
equation (including the asymptotic solution for the dis-
tribution of test particles) within a Fokker-Planck equa-
tion should be independent of the implementation of the 
stocharistic process (i.e., Langevin scheme). Thus, the 
“Ito-Stratonovich dilemma”, which suggests that differ-
ent Langevin prescriptions are not sufficient in order to 
uniquely determine the Fokker-Planck equation, does not 
appear here, as a benefit of a well-defined microscopic 
process.

The Langevin updating rules in the post-point scheme read

$$\begin{align*}
dx_j &= \frac{p_j}{E} \, dt , \\
dp_j &= -\Gamma(p)p_j \, dt + \sqrt{2dtD(|\mathbf{p} + dp|)} \rho_j .
\end{align*}$$  \hfill (26, 27)

Starting with initial coordinate $x$ and momentum $\mathbf{p}$, 
the coordinate update is trivial at given time step $dt$, 
but the momentum update involves a two-step compu-
tation: first use the pre-point scheme Eq. (21) to calcu-
late the momentum increment $dp$ with $\Gamma(p)$ and $D(p)$; 
then evaluate the diffusion coefficient $D$ at the argument 
$|\mathbf{p} + dp|$ and calculate $dp_{\text{diffusion}} = \sqrt{2dtD(|\mathbf{p} + dp|)} \rho_j$, 
while $dp_{\text{drag}} = -\Gamma(p)p_j \, dt$ has already been calculated 
in the first step; finally, add up $dp_{\text{diffusion}}$ and $dp_{\text{drag}}$ to obtain the total momentum increment for the present 
time-step. Note that in the two-step momentum update 
procedure, the same $dt$ and $\rho_j$ should be used. A variant 
where different $dt$’s are used will be discussed in the case of 
a flowing medium in Secs. IV B and IV C below.

IV. NUMERICAL CALCULATIONS WITH DIFFERENT BACKGROUND MEDIA

In this section we perform numerical simulations of the 
two different Langevin prescriptions discussed above 
(and some variants thereof previously employed in the 
literature), to explicitly examine their consequences for 
the long-time limits, in particular in the case of flowing 
media. For definiteness we will adopt parameter values 
for masses, temperature and flow profiles representing the 
problem of heavy-quark diffusion in a QGP. We will start 
with a homogeneous static medium (Sec. IV A), followed 
by a simple one-dimensional diffusion in a QGP (Sec. IV B) 
and finally study a more realistic elliptically expanding fire-
ball (Sec. IV C). In all cases we use large drag and dif-
fusion coefficients and perform the simulations until the
stationary state has been reached, demonstrating their universal convergence to the analytical solutions for the corresponding Fokker-Planck equations.

A. Homogeneous Static Medium

Let us assume a homogeneous static medium with temperature $T = 0.18$ GeV with a Brownian particle of mass $m = 1.5$ GeV immersed (we work in natural units where the velocity of light, Planck constant, and Boltzmann constant are equal to unity: $c = \hbar = k_B = 1$). The preceding Fokker-Planck and Langevin equations can be readily applied; we focus on the projection on the $z$-component of the momentum distribution, $dN/dp_z$, of the test particle. It has been checked that the equilibrium conditions are reached independent of arbitrarily chosen initial conditions, as expected.

We first adopt the pre-point scenario in a simplistic scenario where a large constant friction coefficient ($\Gamma = 20$ fm$^{-1}$) is complemented by a diffusion coefficient $D = \Gamma E$. This leads to a stationary distribution,

$$dN/d^3x d^3p = m/E \exp[-E(p)/T],$$

as shown in the upper panel of Fig. 1. It can be easily verified analytically by plugging the drag and diffusion coefficients into the Fokker-Planck equation and performing the momentum derivatives, as was also discussed in Ref. [2]. However, this form of drag and diffusion coefficient does not comply with the pre-point equilibrium condition, and thus the simulation fails to converge to the Boltzmann-Jüttner distribution.

To illustrate the importance of implementing the proper equilibrium condition, we have performed Langevin simulations within the pre-point scheme using two types of momentum dependencies of the diffusion coefficient:

(i) $\Gamma = 20/E$ GeV/fm;
$$D = \Gamma ET = 20T \text{ GeV/fm.}$$

(ii) $\Gamma = 300(1 + T/E)/E^2$ GeV$^2$/fm;
$$D = 300 T/E \text{ GeV}^2/\text{fm.}$$

The lifetime of the system in these simulations has been set to 10 fm, and it has been checked that the stationary distribution has been reached.

The simulated results are also shown in the upper panel of Fig. 1. Again, their agreement with the Boltzmann-Jüttner distribution can be analytically verified by substituting the coefficients into the Fokker-Planck equation and carrying out the momentum derivatives.

Next, we employ the post-point scenario. The simulated results are shown in the lower panel of Fig. 1. Here, the Langevin simulations with large drag reproduce well the Boltzmann-Jüttner distribution, whether the friction is constant ($\Gamma = 20$/fm, $D = \Gamma ET$) or not ($\Gamma = 40\sqrt{\text{GeV fm}^{-1}}/\sqrt{E(p)}, D = \Gamma ET$), since the post-point equilibrium condition is always fulfilled. This is easily verified by plugging the coefficients into the corresponding Fokker-Planck equation.

To summarize this part, we have confirmed through numerical simulations that in order for the stationary Langevin limit to converge to the Boltzmann-Jüttner distribution, the equilibrium condition must be exactly fulfilled.

B. Constant 1-D Flow

We now introduce a constant one-dimensional medium flow with velocity field $v_x = 0, v_y = 0$ and $v_z = 0.9$. The medium temperature, $T = 0.18$ GeV, and heavy-quark mass, $m = 1.5$ GeV, are as before.

The numerical simulations in the pre-point scheme directly translate the result for the static medium into the corresponding “blast-wave” distribution, obtained by replacing $E$ with $\mathbf{p} \cdot \mathbf{u}$. Specifically, a momentum-independent drag complemented by the naive $D = \rho \mathbf{u}$.

![FIG. 1: The distribution, $dN/dp_z$, from Langevin simulations for heavy quarks with mass $m = 1.5$ GeV, diffusing in a static medium at temperature $T = 0.18$ GeV, compared to calculations with the corresponding analytical phase-space distributions: (a) pre-point Langevin scheme, (b) post-point Langevin scheme. See the text for more details.](image)
\(\Gamma ET\) leads to a single-particle phase-space distribution \(dN/d^3xd^3p = m/(p \cdot u) \exp(-p \cdot u/T)\), while general momentum-dependent coefficients that fulfill the pre-point equilibrium condition \(19\) give the Boltzmann-Jüttner distribution, \(dN/d^3xd^3p = \exp(-p \cdot u/T)\), see upper panel of Fig. \[IV\ B\].

For the post-point scenario, where the equilibrium condition takes the simple form \(23\), the momentum update involves two steps in the fluid-rest frame. There seems to be an ambiguity in the time increment \(dt^*\) used in the two-step computation (here and in the following, variables with (without) superscript * refer to the fluid rest (laboratory) frame). For the first step, it is clear that \(dt^*_{(1)} = dt \frac{E^*_{(1)}}{E_{(1)}} = dt \frac{E_{(1)}}{p^0}\) with \(E = p^0\) being the lab-frame energy prior to the momentum update and \(E^* = p \cdot u\) the corresponding energy measured in the fluid rest frame. One then updates the momentum and obtains \(p^*_{(1)} = (E^*_{(1)}, p^*_{(1)})\) in the fluid rest frame; the corresponding lab-frame four-momentum, \(p^*_{(1)} = (E_{(1)}, p_{(1)})\), follows from a boost using the fluid velocity \(u^\mu\). In the subsequent second-step momentum update, one finds a particle phase-space distribution, \(dN/d^3xd^3p = (p \cdot u/p^0) \exp(-p \cdot u/T)\) in the lab frame if one uses \(dt^*_{(2)} = dt \frac{E^*_{(2)}}{E_{(1)}} = dt \frac{p_{(1)}^0}{E_{(1)} \neq dt^*_{(1)}}\). This is different from the Boltzmann-Jüttner distribution (we denote it as a "variant"), as illustrated in the lower panel of Fig. \[IV\ B\]. One finds both analytically and numerically that the Boltzmann-Jüttner distribution is recovered when using \(dt^*_{(2)} = dt^*_{(1)}\) in the second-step momentum update. Recalling that in the general derivation of Fokker-Planck equation from the Langevin equations \(11\) (for a static thermal medium) a fixed \(dt^* = dt^*_{(1)}\) is adopted, we conclude that in the post-point scheme, one should use the same \(dt^* = dt^*_{(1)}\) for both momentum-update steps in order to obtain the Lorentz-invariant Boltzmann-Jüttner distribution in the presence of flow.

![Graph](image1.png)

**FIG. 2:** Langevin simulation results for heavy quarks \((m = 1.5 \text{ GeV})\) diffusing in a flowing medium \((T = 0.18 \text{ GeV}, v_s = 0.9)\) compared to calculations with analytical phase-space distributions: (a) pre-point Langevin scheme, (b) post-point Langevin scheme. The distribution obtained with a variant of post-point scheme and the corresponding blast-wave distribution are also shown. See text for more details.

![Graph](image2.png)

**FIG. 3:** Langevin simulation of the \(p_T\)-spectrum of a heavy quark \((m = 1.5 \text{ GeV})\) diffusing in a fireball \((T_i = 0.33 \text{ GeV}, T_f = 0.18 \text{ GeV})\), compared to the direct blast wave calculations. Upper panel: pre-point Langevin scheme; lower panel: post-point Langevin scheme. See text for more details.
C. Elliptic Fireball

In non-central heavy-ion collisions, interactions among particles convert the initial spatial asymmetry into particle momentum anisotropies, most notably an “elliptic flow” quantified by the coefficient of the second harmonic, $v_2(p_T)$, in the azimuthal-angle distribution of the particle spectrum \[16, 17\],

\[
\frac{dN}{p_T dp_T d\phi_p} = \frac{dN}{2\pi p_T dp_T} [1 + \pi v_2(p_T) \cos(2\phi_p) + \cdots], \quad (31)
\]

where $p_T$ is the transverse momentum of the emitted particle. Heavy quarks (or hadrons containing heavy quarks) are believed to acquire a $v_2$ through the coupling to the collective motion of the light particles in the QGP \[8, 11\].

In the following, we employ an elliptically expanding fireball, introduced in Ref. \[27\] (see also the discussion in Ref. \[28\] for more details) to model the QGP medium evolution, in order to scrutinize the Langevin simulation of heavy-quark (HQ) diffusion in the QGP background. We again take the HQ mass to be $m = 1.5$ GeV and employ the same two sets of coefficients $\Gamma$ and $D$ as specified in Eqs. (29) and (30), satisfying the equilibrium conditions. This time the Langevin simulation runs in parallel to an isentropically expanding fireball which stops at the decoupling temperature $T_f = 0.18$ GeV. We compute the spectrum and elliptic flow and compare to the results of a direct blast-wave calculation which corresponds to the equilibrium limit of the fireball.

Let us first discuss the HQ $p_T$-spectrum, shown in Fig. 3. For the pre-point scenario (upper panel), Langevin simulation results translate again directly into the corresponding blast-wave distributions (obtained by replacing $E$ with $p \cdot u$). For a momentum-independent drag coefficient complemented by the naive $D = \Gamma ET$ (at variance with the equilibrium condition), the HQ phase-space distribution assumes the form $dN/d^3xd^3p = m/(p \cdot u) \exp(-p \cdot u/T)$, while general momentum-dependent coefficients that fulfill the pre-equilibrium condition \[15\] accurately recover the Boltzmann-Jüttner distribution $dN/d^3xd^3p = \exp(-p \cdot u/T)$. For the post-point scenario (lower panel), again, once the corresponding equilibrium condition \[29\] is satisfied, the Langevin simulation also yields the correct Lorentz-invariant Boltzmann distribution, while the “variant” scheme leads to an explicitly frame dependent distribution $dN/d^3xd^3p = (p \cdot u/p^2) \exp(-p \cdot u/T)$. This results from using a different $d_3^f \neq d_3^e$ in the two-step momentum update, as discussed in Sec. IV.B.

The HQ $v_2(p_T)$ obtained from the equilibrium limit of the Langevin simulations and its comparison with the direct blast-wave calculations are shown in Fig. 4. The agreement between different implementations (pre-point, post-point and variants) of Langevin simulations and the corresponding blast-wave distributions confirm the conclusions for the $p_T$ spectra, reproducing accurately even rather subtle angular modulations in relativistic flow fields.

![FIG. 4: Langevin simulation results for $v_2(p_T)$ for a heavy quark ($m = 1.5$ GeV) diffusing in a QGP ($T_f = 0.18$ GeV) compared to direct blast-wave calculations with the flow field and temperature of the background medium (fireball). Upper panel: pre-point Langevin scheme; lower panel: post-point Langevin scheme.](image)

V. SUMMARY AND CONCLUSIONS

In this work we have explored aspects of relativistic Langevin dynamics, in particular their uniqueness relative to a Fokker-Planck description and their manifestation in the presence of non-trivial medium-flow fields. Our perspective on these issues commenced from a microscopic theory for the interactions of a Brownian particle in a fluid of light particles, where the Fokker-Planck equation emerges from the Boltzmann equation with well-defined transport coefficients. We thus started by re-establishing the general constraint between the drag and diffusion coefficients in order for the asymptotic solution of the Fokker-Planck equation to converge to the Boltzmann-Jüttner distribution in the equilibrium limit. Based on this “master equation” we investigated two widely used Langevin realizations of the Fokker-Planck equation and explicitly obtained the equilibrium conditions for the coefficients in these schemes. It followed that both pre-point and post-point Langevin equations obey...
an equivalent Fokker-Planck equation in terms of the original drag and diffusion coefficients, thus illuminating the “Ito-Stratonovich dilemma”, i.e., the pre-point and the post-point Langevin algorithm turn out to be equally adequate to describe the same micro-physics. We verified these results by explicit numerical simulations, recovering the Boltzmann-Jüttner distribution as the equilibrium limit of heavy test particles, if and only if the corresponding equilibrium condition is implemented exactly. We furthermore confirmed that the Langevin dynamics preserves the Lorentz invariance of the particles’ phase-space distribution in the presence of collective-flow fields of the background medium: the particle’s energy in the fluid rest frame, $E^*$, simply converts into $p \cdot u$, where $p$ is the particle’s four momentum in the lab frame, and $u$ is the fluid four-velocity. This, in particular, showed the fulfillment of Lorentz-covariance through the two levels of approximation from full Boltzmann transport to the Langevin process. We believe that these insights are, in particular, useful for reliable simulations of heavy-quark diffusion in heavy-ion collisions, where the coupling of the Brownian particle to the rather subtle relativistic flow fields has become a quantitative tool to extract transport properties of the background medium.
