Abstract

Hair follicles undergo recurrent cycling of controlled growth (anagen), regression (catagen), and relative quiescence (telogen) with a defined periodicity. Taking a genomics approach to study gene expression during synchronized mouse hair follicle cycling, we discovered that, in addition to circadian fluctuation, CLOCK-regulated genes are also modulated in phase with the hair growth cycle. During telogen and early anagen, circadian clock genes are prominently expressed in the secondary hair germ, which contains precursor cells for the growing follicle. Analysis of Clock and Bmal1 mutant mice reveals a delay in anagen progression, and the secondary hair germ cells show decreased levels of phosphorylated Rb and lack mitotic cells, suggesting that circadian clock genes regulate anagen progression via their effect on the cell cycle. Consistent with a block at the G1 phase of the cell cycle, we show a significant upregulation of p21 in Bmal1 mutant skin. While circadian clock mechanisms have been implicated in a variety of diurnal biological processes, our findings indicate that circadian clock genes may be utilized to modulate the progression of non-diurnal cyclic processes.

Introduction

Evolutionarily conserved hair follicle cycling is thought to provide mechanisms for controlling the length of hair in specific body sites, and to allow the periodic shedding of fur in response to seasonal changes in mammals [1]. The periodicity of the hair growth cycle ranges from approximately three-weeks in synchronized hair follicles of mouse dorsal skin to several years in hair follicles of human scalp where the follicles undergo an extended period of hair growth [2]. In mice, hair follicle morphogenesis is completed around postnatal day (P) 14, at which time the follicle enters a phase called catagen. During catagen, extensive apoptosis in the lower two-thirds of the follicle results in its dramatic regression, leaving intact the stem cell-containing bulge region. The hair follicle then goes through a relative quiescent phase referred to as telogen. Following telogen, the stem cells become activated, likely in response to inductive signals from the dermal papilla, and the follicle enters the growth phase characterized by active keratinocyte proliferation and differentiation known as anagen. During the first two natural hair growth cycles in mice, the follicles of the dorsal skin are synchronized in progressing through the cycle, allowing the study of the mechanisms of natural hair follicle cycling. In addition, tightly synchronized hair growth cycle can be initiated by depilation of hair shafts (e.g., waxing) during the telogen phase, with the caveat, however, of triggering an injury response [3]. Although components of numerous molecular pathways, including TGFβ/BMP family members and their antagonists, FGFs and steroid hormone receptors, have been implicated in the control of hair follicle cycling [1,4–8], the underlying mechanisms regulating its timing remain elusive [9].

The periodicity of the hair growth cycle is reminiscent of other cyclic processes, such as the circadian rhythm where distinct clock mechanisms exist. The regulation of circadian rhythm consists of positive and negative regulatory feedback loops, having a period of approximately 24 hours [10–12]. The positive feedback loop is regulated by two DNA-binding basic helix-loop-helix (bHLH) PAS domain transcription factors CLOCK and BMAL1 [13], which form a heterodimer and transcriptionally activate genes containing E-boxes in their regulatory regions. Among their targets are PER (PER 1, 2 and 3) and CRY (CRY1 and 2) that form heterodimers and repress their own transcription via direct interactions with CLOCK/BMAL1 [14]. Additional targets include RORs (Rora, Rorb, and Rorc) and REV-ERBs (Nr1d1 and Nrd2), which are members of a subfamily of orphan nuclear receptors that bind to ROR response elements (RREs) to transcriptionally activate and repress Bmal1, respectively [15,16]. Other CLOCK-controlled targets, such as the transcription factors DBP and TEF, are not
part of the central circadian mechanism, but are thought to mediate many of its physiological effects [17,18].

In mammals, the central pacemaker that controls circadian behavior is in the suprachiasmatic nucleus (SCN) of the hypothalamus. It is now widely accepted that the circadian control mechanisms are not limited to the SCN, but instead, the molecular clock is expressed and operative in most peripheral tissues [19–21]. Increasing evidence highlights the importance for the SCN in coordinating the independent oscillation of molecular clocks in peripheral tissues [10]. Although several studies demonstrated circadian rhythm within human and mouse skin as well as oral keratinocytes [22–26], a functional role for the circadian clock genes in skin has yet to be determined. Taking a genomics approach to study gene expression during synchronized mouse hair follicle cycling, we discovered that the genes which control circadian rhythm are utilized to modulate the progression of hair follicle cycling, a biological process of much longer duration than the diurnal period. We found a significant delay in anagen progression in both Clock and Bmal1 mutant mice, and the secondary hair germ cells within mutant hair follicles show decreased levels of phosphorylated Rb and lack mitotic cells, suggesting the circadian clock modulates anagen progression via its effect on the cell cycle.

Results
Identification of Periodically Expressed Genes during Hair Follicle Cycling from Time-Course Expression Profiles
To investigate the molecular control of hair follicle cycling, we profiled mRNA expression in mouse dorsal skin at multiple time points in the synchronized second postnatal hair growth cycle and in a depilation-induced hair growth cycle. By combining this data with a study profiling the postnatal completion of hair follicle morphogenesis as well as the first catagen and telogen [27], we obtained genome-wide time-course expression profiles for three distinct hair growth cycles (Figure 1A and 1B). To detect genes with periodic expression changes over multiple hair growth cycles, we constructed a probabilistic model with periodic and background components (graphical model shown in Figure 1C). The periodic component includes a mixture model of shared periodic expression profiles and allows deviation from perfect periodicity due to initial hair follicle morphogenesis or injury response to depilation. Given this model structure and observed data, we used Bayesian inference techniques to infer periodic profiles and posterior probability of periodicity for each of the probe sets [28] (Text S1).

Applying this model to the 28,341 expressed probe sets, we found that 8433 probe sets have posterior probability of greater than 0.95 of being periodically expressed (Figure 1D, top panel). Probe sets with periodic profiles over the hair growth cycle were further narrowed to 6399 probe sets exhibiting periodic gene expression changes that cannot be explained by changes in tissue composition (Figure S1); we define this set of genes as hair cycle-regulated genes (Figure 1B and Table S1). To assess the sensitivity of the calculated posterior probabilities, we compiled a list of literature-based hair cycle-dependent genes from a comprehensive unbiased literature search of genes whose expression patterns have been shown to be hair cycle-dependent using quantitative or semi-quantitative RNA methods (Table S2). We found that over 80% of literature-based hair cycle-dependent genes have posterior probabilities of greater than 0.95 (Figure 1D, bottom panel); for genes that have posterior probabilities of lower than 0.95, their expression profiles either do not visually appear to be periodic or are detected at a low intensity level. From these findings, we conclude that our probabilistic model is accurate and robust in identifying periodic expression changes during hair follicle cycling.

Distinct Functional Groups of Genes Are Activated at Different Phases of Hair Follicle Cycling
To identify genes which are activated at specific phases of the hair growth cycle, we performed statistical differential analysis of hair cycle-regulated genes by comparing the expression from one phase to the next (e.g., genes upregulated at early anagen are significantly differentially expressed genes between telogen and early anagen samples). We then searched for significantly enriched Gene Ontology (GO) Biological Process categories within the different sets of genes upregulated at specific phases of the hair growth cycle. Among the genes upregulated at early anagen is a significantly overrepresented number of cell cycle and DNA/RNA metabolism genes, as well as other genes that are required during proliferation (Figure 1E). Many of the other enriched functional categories are also expected based on our current knowledge of hair follicle biology, validating the value of this approach. For example, members of the Hedgehog signaling pathway are upregulated during early anagen (Figure S2), consistent with their role in proliferation of keratinocytes. In contrast, TGFβ/BMP signaling pathway genes are upregulated towards the later stages of anagen, and these genes have been reported to be involved in hair follicle differentiation and apoptosis. In addition to identifying several pathways known to be involved in hair follicle regulation [1,4–7], our enrichment analysis identified functional categories that were unexpected, potentially providing novel insights into regulation of hair follicle cycling. For instance, telogen is often referred to as the “quiescent phase” of the cycle, but we found significantly enriched group of genes annotated with the function of generation of precursor metabolites and energy (P = 1.97E-4) and establishment of localization (P = 3.39E-2) that are upregulated during telogen, suggesting that many active molecular processes are occurring during telogen (Figure 1E).

CLOCK–Regulated Genes Are Periodically Expressed in Phase with the Hair Growth Cycle
To uncover the genome-wide landscape of transcriptional regulation during hair follicle cycling, we performed time-course
Figure 1. Identification of hair cycle-regulated genes using probabilistic models. (A) Representative time points selected for gene expression profiling of the natural and depilation-induced hair growth cycles. Time points for natural cycles represent postnatal days, and time points for depilation-induced cycle indicate the number of days following depilation. Since the three cycles have different duration, the schematic timeline is not in actual time scale. Bottom panel consists of representative histology of dorsal skin at key phases of synchronized hair follicle cycling. (B) Overview of data processing and statistical analyses. Note that samples for the first synchronized hair growth cycle and asynchronous time points were profiled in an earlier study using an older generation array (Affymetrix Murine Genome U74Av2). (C) Schematic of the probabilistic model for detection of periodic gene expression changes during hair follicle cycling. See Materials and Methods for a detailed description of the schematic. Asynch – asynchronous cycle. (D) Histogram of the number of probe sets within each range of the indicated posterior probabilities. Top panel is the histogram of probabilities for all present genes during the hair growth cycle. The bottom panel is the histogram of probabilities for the literature-based hair cycle-dependent genes. (E) List of significantly enriched GO Biological Process categories within the sets of genes specifically upregulated at the indicated phases of the hair growth cycle. Due to the redundancy of categories, not all are listed. The number of genes upregulated at each phase of the cycle is in parentheses. Statistical enrichment of each category is shown as P-values calculated using a modified Fisher Exact test (DAVID functional annotation analysis).

doi:10.1371/journal.pgen.1000573.g001
clustering of all hair cycle-regulated transcriptional regulators. Remarkably, this genome-wide landscape grouped together many of the key transcription factors previously shown to be functionally important during hair follicle morphogenesis and/or cycling (Figure 2A). Mice with mutations to these transcription regulators show abnormalities in hair follicle density (Lef1, Msx1, Msx2, Sox18, Trps1), structure (Dlx3, Foxn1, Foxq1, Hoxc13, Notch1, Oox11, Runx1), morphogenesis (Ctnnb1, Cal1, Gli2, Lef1, Msx2, Smad7), and cycling (Hr, Msx2, Stat5, Vdb).

Among the hair cycle-regulated transcriptional regulators, we were intrigued to identify a co-expressed cluster of transcription factors that are targets of circadian protein CLOCK, including Dbp, Per1, Per2, Cry2, Nrl1, Tef and Hlf (Figure 2A); a hair follicle cycle-related expression of these genes has not been previously described. Correspondingly, in the set of genes significantly upregulated at telogen we also found a statistical enrichment of the GO annotation category rhythmic processes (Figure 1E). A time course expression profile covering hair follicle morphogenesis and the synchronized postnatal hair growth cycles shows upregulation of these CLOCK-regulated genes during telogen phases (Figure 2B). In an independent Q-PCR experiment, we confirmed up-regulation of Dhp around the first and second telogen, and found that the expression stays elevated during early anagen (Figure 2C). However, without a suitable DBP antibody for western/immunohistochemistry, we were unable to determine whether this upregulation of Dhp transcript levels is reflected in increased protein levels. The levels of PER2 proteins in whole skin, however, do not appear to be different between telogen and late...

Figure 2. CLOCK–regulated genes are periodically expressed during hair follicle cycling. (A) Temporal clusters (labeled 1–6 and color coded) of hair cycle-regulated transcriptional regulators. Transcription factors that play key roles in hair follicle morphogenesis and/or cycling are labeled with gene symbols in black. CLOCK-regulated genes are labeled in the blue box. Expression levels are from profiling data of the second hair growth cycle and are indicated by the colorimetric ratio-scale. (B) Time-course profiles of CLOCK-controlled genes during hair follicle morphogenesis, the first two natural and depilation-induced hair growth cycles. For each gene, the expression levels were normalized relative to the lowest expressed time point of the second cycle; the first cycle (P1 to P23) was normalized separately because different array was used for profiling. Differences in magnitude of change between the first and second cycles are primarily due to differential probe set efficiencies. Note the broken y-axis. E – embryonic days; P – postnatal days; D – depilation days. (C) Q-PCR of Dhp using independent samples from the first two synchronized hair growth cycles. Standard deviations were determined by using three replicates normalized to Gapdh and fold calculated relative to the lowest expression sample. For (B–D), time points are mapped based on histology to the corresponding phases of the cycle: hair follicle morphogenesis (M), anagen (A), catagen (C), and telogen (T).

doi:10.1371/journal.pgen.1000573.g002
anagen (Figure S3C). Thus, in murine skin, CLOCK-regulated genes unexpectedly exhibit periodic expression in phase with the hair growth cycle, a cyclic process with a much longer time scale than circadian rhythms.

CLOCK–Regulated Genes Have Enhanced Circadian Expression during Telogen

The expression of CLOCK-regulated genes oscillates over a 24-hour period [10–12], while we observed a hair cycle-associated oscillation over a period of several weeks (Figure 2). Therefore, to understand the nature of the up-regulation of these genes during telogen, we performed Q-PCR for Dbp, Nrl1d1, Per2, Bmal1, and Clock of telogen and late anagen mouse dorsal skin over the course of 48 hours of normal light/dark cycles (Figure 3). For Dhp, Per2, and Nrl1d1, we observed circadian oscillations of expression in both telogen and late anagen, but the amplitude of the oscillation is significantly enhanced during telogen (Figure 3C–3E). The peak expression of Dhp and Nrl1d1 is approximately 3-fold higher (P<0.01) in telogen than late anagen. Similar to other peripheral tissues, such as the liver approximately 3-fold higher (Figure 3C–3E). The peak expression of the oscillation is significantly enhanced during telogen.

Prominent Expression of Clock Genes in the Secondary Hair Germ during Telogen and Early Anagen

To identify the potential site of action for circadian mechanisms, we characterized the in situ skin expression of Bmal1 and its target gene Dhp, a robust marker for clock output [18]. During telogen and early anagen, the most striking site of expression for both genes is in the secondary hair germ, an epithelial compartment located next to the dermal papilla (Figure 4 and Figure S3A). Interestingly, the secondary hair germ is derived from hair follicle bulge epithelial stem cells [29] and contains Lgr5-positive cells, a recently described multipotent stem cell population that is actively proliferating [30]. Keratinocytes of this compartment are the first to show robust proliferation at the onset of anagen [3], and are the progenitor cells for the anagen hair bulb, pigmented hair shaft, and inner root sheath [31–33]. As expected, Dhp expression is attenuated in the secondary hair germ of telogen hair follicles at ZT2 (Figure 4I). Bmal1 and Dhp are also expressed in the lower regions of the late anagen and catagen hair follicles, as well as the epidermis and dermis throughout the hair growth cycle. Q-PCR of laser captured microdissected hair follicles, dermis, and epidermis indicate that clock genes are differentially expressed between ZT10 (high) and ZT18/ZT2 (low) in the dermis and epidermis during both telogen and late anagen (Figure 4J and Figure S4), consistent with previous studies in human skin [23,25]. Interestingly, there is more active circadian regulation of these genes within the hair follicle proper during telogen compared to late anagen (Figure 4J and Figure S4), which likely contributes to the increased amplitude in expression during telogen. In summary, these data show that Bmal1 and Dhp are widely expressed within hair follicles and other skin compartments throughout hair follicle cycling. However, during the important stage of initiation of hair growth at telogen and early anagen, the expression of these genes is prominent in the secondary hair germ of the hair follicle.

Activation of CLOCK–Regulated Genes in Skin Is CLOCK/BMAL1–Dependent

To determine whether the expression of CLOCK-regulated genes in skin is dependent on CLOCK/BMAL1 activation, we profiled the dorsal skin of Bmal1+/− and Bmal1−/− control littermates at P22, when the hair follicles for both genotypes are in the first synchronized telogen (Figure 5A). Consistent with the mammalian circadian transcriptional circuit, functional annotation analysis of the 339 probe sets that are significantly differentially expressed in Bmal1−/− skin identified statistical enrichment (P=5.7E-8) of genes annotated with the GO category of rhythmic processes (i.e., circadian clock genes). Specifically, clock genes with E/E′ or D-box in their regulatory regions (e.g., Nrl1d1, Nrl1d2, Per1, Per2, Per3, Dhp, and Bhlhb3) are significantly downregulated in Bmal1−/− mice (Figure 5B) [17], consistent with attenuated transcriptional activation by the CLOCK/BMAL1 heterodimer. The downregulation of Nrl1d1 and Nrl1d2 relieves the transcriptional repression of clock genes with RREs in their regulatory regions (e.g., Clock, Bmal1, Nrho2, Cyl1, Nfils, and Rorc), resulting in significant upregulation of RRE-containing clock genes in Bmal1−/− skin (Figure 5B) [17]. We confirmed by Q-PCR the significant differential expression of CLOCK-regulated genes in Bmal1 and Clock mutant skin (Figure 5C and 5D), indicating that the activation of these genes is CLOCK/BMAL1-dependent in skin.

A particularly intriguing finding of the microarray analysis of Bmal1−/− skin is the significant differential expression of Rorc and Nrl1d1 (Figure 5B). Rorc, which was recently shown to be a critical transcriptional activator of the G1 cell cycle regulator Cdkn1a (p21) [34], is upregulated approximately 3-fold (Figure 5C). Conversely, Nrl1d1, a repressor of Cdkn1a expression [34], is downregulated approximately 15-fold. Consistent with these changes, we found that Cdkn1a is upregulated 2.5-fold (Figure 5C). With the exception of Weel, which has been shown to be a CLOCK/BMAL1 target gene [35], other cell cycle regulators (e.g., Cdkn1b, Cdkn2b, and Cdkn2a) are not significantly differentially expressed in Bmal1−/− skin (Figure 5C). Together, these results show that Cdkn1a, an important inhibitor of cell cycle progression, is upregulated in the skin of Bmal1−/− mice, suggesting the possibility that clock genes may regulate cell proliferation within skin.

Delayed Anagen Progression in Bmal1 and Clock Mutant Mice

To determine whether circadian regulators play a functional role in the hair growth cycle, we studied the progression of synchronized hair follicle cycling in Bmal1−/− mice [36]. While the completion of hair follicle morphogenesis (P14) and entry into telogen (P21) are normal, there is a clear delay at the first synchronized anagen (P22) when the hair follicles for both genotypes are in the first synchronized telogen (Figure 5A). Consistent with the mammalian circadian transcriptional circuit, functional annotation analysis of the 339 probe sets that are significantly differentially expressed in Bmal1−/− skin identified statistical enrichment (P=5.7E-8) of genes annotated with the GO category of rhythmic processes (i.e., circadian clock genes). Specifically, clock genes with E/E′ or D-box in their regulatory regions (e.g., Clock, Bmal1, Nrho2, Cyl1, Nfils, and Rorc), resulting in significant upregulation of RRE-containing clock genes in Bmal1−/− skin (Figure 5B) [17]. Consistent with attenuated transcriptional activation by the CLOCK/BMAL1 heterodimer. The downregulation of Nrl1d1 and Nrl1d2 relieves the transcriptional repression of clock genes with RREs in their regulatory regions (e.g., Clock, Bmal1, Nrho2, Cyl1, Nfils, and Rorc), resulting in significant upregulation of RRE-containing clock genes in Bmal1−/− skin (Figure 5B) [17]. We confirmed by Q-PCR the significant differential expression of CLOCK-regulated genes in Bmal1 and Clock mutant skin (Figure 5C and 5D), indicating that the activation of these genes is CLOCK/BMAL1-dependent in skin.

A particularly intriguing finding of the microarray analysis of Bmal1−/− skin is the significant differential expression of Rorc and Nrl1d1 (Figure 5B). Rorc, which was recently shown to be a critical transcriptional activator of the G1 cell cycle regulator Cdkn1a (p21) [34], is upregulated approximately 3-fold (Figure 5C). Conversely, Nrl1d1, a repressor of Cdkn1a expression [34], is downregulated approximately 15-fold. Consistent with these changes, we found that Cdkn1a is upregulated 2.5-fold (Figure 5C). With the exception of Weel, which has been shown to be a CLOCK/BMAL1 target gene [35], other cell cycle regulators (e.g., Cdkn1b, Cdkn2b, and Cdkn2a) are not significantly differentially expressed in Bmal1−/− skin (Figure 5C). Together, these results show that Cdkn1a, an important inhibitor of cell cycle progression, is upregulated in the skin of Bmal1−/− mice, suggesting the possibility that clock genes may regulate cell proliferation within skin.
Figure 3. Enhanced circadian expression of CLOCK–regulated genes during telogen. Q-PCR of Bmal1 (A), Clock (B), Dbp (C), Per2 (D), and Nr1d1 (E) in telogen compared to late anagen dorsal skin over the course of 48 hours (open and filled bars along the x-axis denote 12 hours light and dark phases, respectively). Expression is normalized to Gapdh and fold calculated relative to the lowest expression time point for both telogen and late anagen. Each error bar represents the S.E.M. for independent measurements from four mice. Asterisks denote significantly higher (P<0.01) expression of Dbp and Nr1d1 at ZT10 in telogen.

doi:10.1371/journal.pgen.1000573.g003
in an overall shift of the hair growth cycle, while the duration of the entire hair growth cycle is not altered in Bmal1<sup>−/−</sup> mice. In Clock mutant mice [37,38], we found a similar but less prominent delay in progression into the first synchronized anagen (Figure 6B and Table S4). We observed no obvious morphological abnormalities in the hair follicles of Bmal1 and Clock mutant mice (Figure S5A). Hence, the delayed anagen progression in both Clock and Bmal1 mutant mice—without abnormalities in hair follicle morphogenesis, basic architecture, pigmentation, and hair shaft formation—points to clock genes as important regulators of timing in hair follicle cycling.

Circadian Clock Genes Regulate Cell Cycle Progression in the Secondary Hair Germ of Hair Follicles

Since circadian mechanisms are implicated in cell cycle control [34,35,39,40], and we found upregulation of Cdkn1a in Bmal1<sup>−/−</sup> mouse skin, we next examined whether Bmal1<sup>−/−</sup> hair follicles exhibit alterations in cell cycle control. Interestingly, we observed an absence of mitotic cells within the hair follicles delayed at anagen I of P24 Bmal1<sup>−/−</sup> mice (Figure 6F); both Bmal1<sup>+/−</sup> and Bmal1<sup>−/−</sup> littermates have mitotic cells interspersed in the basal layer of epidermis, indicating a hair follicle-specific effect of the Bmal1 mutation. This is significant because hair follicles of P23 wild-type mice, which are morphologically equivalent (in anagen I) to hair follicles of P24 Bmal1<sup>−/−</sup> mice, are molecularly distinct in that they contain mitotic cells in the secondary hair germ (Figure 6F, third panel), the site of high Dbp expression during early anagen. Both highly proliferative matrix cells of P24 Bmal1<sup>+/−</sup> hair follicles and the secondary hair germ cells of P23 wild-type hair follicles contain phosphorylated Rb (Figure 6G). In contrast, phosphorylated Rb was not detected in the secondary hair germ cells of P24 Bmal1<sup>−/−</sup> hair follicles of the same hair cycle stage (Figure 6G, third panel), indicating a blockade of secondary hair germ cells in G1. Thus, circadian clock genes may control hair follicle cycling at least in part by regulating proliferation in the secondary hair germ of the early anagen follicle.

**Figure 4. Bmal1 and its target gene Dbp are co-expressed during hair follicle cycling.** In situ hybridization staining of telogen, early anagen, late anagen, and catagen dorsal skin at ZT10 with Bmal1 (A–D) and Dbp (E–H) probes. (I) Dbp expression at ZT2 in telogen skin. Dashed lines indicate border between epidermis and dermis. Note that the black pigment of the hair shaft in late anagen hair follicles is not hybridization signal. Bu – bulge, CH – club hair, DP – dermal papilla, HB – hair bulb, HS – hair shaft, IRS – inner root sheath, Mx – matrix, ORS – outer root sheath, SHG – secondary hair germ, SG – sebaceous gland. (J) Dbp expression from laser capture microdissected hair follicles, dermis, and epidermis for telogen and late anagen dorsal skin at ZT10 and ZT18/ZT2. Standard deviations were determined by using three replicates normalized to Gapdh. Ct values indicate detectable expression of clock genes in every sample, and fold was calculated relative to the lowest expression sample.
doi:10.1371/journal.pgen.1000573.g004
In summary, our findings demonstrate a novel role for circadian clock genes in modulating the progression of the hair growth cycle, a cyclic biological process that has a much longer duration than the diurnal period. The fact that hair follicles of Bmal1 and Clock mutant mice are specifically impeded in the first stage of anagen, and that clock genes are highly expressed in the secondary hair germ during telogen and early anagen, points to an important role for circadian clock genes in the control of this stage of hair follicle cycling. The delay in anagen progression is likely due to a block at the G1 phase of the cell cycle in the secondary hair germ cells, as these cells lack phosphorylated Rb and Cdkn1a (p21) is upregulated in Bmal1<sup>−/−</sup> mice. Together, these results suggest that the circadian clock modulates progression of hair follicle cycling via its effect on the cell cycle. The recurrent cycling of hair follicles through growth, regression, rest, and then growth again is a classical example of a regenerating system [1]. Thus, it is interesting that clock mechanisms in proliferation seems to become especially important during tissue regeneration, as evident by the impaired liver regeneration after hepatectomy in Cry-deficient mice [33].

Anagen eventually proceeds in Bmal1 and Clock mutant mice, and this could be due to the proposed modulatory role (i.e., non-obligatory) of the circadian clock in regulating the cell cycle machinery [12,40]. A delay rather than a permanent block in anagen progression is also found in many of the previously described mutant mouse models of key regulators in hair follicle cycling [41,42], which may be due to functional redundancies of bHLH PAS transcription factors. One of these transcription factors, NPAS2, has been shown to form heterodimers with BMAL1 to activate circadian-controlled genes in both central and peripheral tissues [43,44]. Intriguingly, Npas2 is regulated during hair follicle cycling (Table S1) and is significantly upregulated in Bmal1<sup>−/−</sup> skin (Figure 6C). A likely explanation for the less pronounced delay in anagen progression in Clock mutant compared to Bmal1<sup>−/−</sup> mice is the difference in the nature of the genetic defects (reduced transcriptional activity in Clock mutant and null-mutation in Bmal1<sup>−/−</sup> mice); similar differences were found in previous studies showing less severe circadian phenotypes in Clock mutant mice [12]. It is important to note that the observed anagen progression delay in Bmal1 and Clock mutant mice is in the context of completely normal morphological features for all compartments of the skin, including hair follicles, sebaceous...
Figure 6. Bmal1 and Clock regulate anagen progression in hair follicle cycling. (A) Representative histological sections of dorsal skin from Bmal1−/− mice and their gender-matched Bmal1+/− littermates at the indicated postnatal age (P). Materials and Methods

Ethics Statement

All animals were handled in strict accordance with good animal practice as defined by the relevant national and/or local animal welfare bodies, and all animal work was approved by the appropriate committee.

RNA Extraction and Time-Course Microarray Experiments

For profiling of second synchronized and depilation-induced hair growth cycle, the same upper-mid region of dorsal skin was excised from C57BL/6 mice at representative postnatal days. Depilation-induced hair growth cycle was performed by applying wax/rosin mixture on the dorsal skin of seven-week old mice (all follicles in telogen). Animals were maintained under alternating 12 hours light/dark cycles with lights on at 6AM, and dorsal skin tissues were collected within 4-hour window (noon to 4PM). Histological sections were used to classify each sample into specific phases/stages of the hair growth cycle based on established morphological guidelines [3]. Total RNA was isolated from adjacent dorsal skin using the TRIzol method (Invitrogen) and cleaned using RNeasy Mini Kit (Qiagen). Quality of cleaned-up RNA was assessed using the Agilent 2100 Bioanalyzer (Agilent) prior to hybridization to Affymetrix Mouse Genome 430 2.0 arrays as described [27]. For each time point, multiple biological replicates were profiled, with each sample separately hybridized to an array (a total of 69 arrays used for profiling three hair growth cycles). The entire time-course wild-type microarray datasets are
Tissue Composition Changes

Determination of Gene Expression Changes Due to Preprocessing of Microarray Datasets

deposited in the NCBI Gene Expression Omnibus (www.ncbi.nlm.nih.gov/geo, GSE11186).

Preprocessing of Microarray Datasets

Based on Principle Component Analysis of all samples and expression of housekeeping genes (e.g., beta-Actin, Gapdh), sample outliers are removed from downstream analyses. To remove genes not expressed during the hair growth cycle, we used MAS 5.0 generated present/absent calls to filter out genes that are not expressed in the dorsal skin at any sampled time point. A two-component noise model (TCM) was then applied to transform the MAS 5.0 expression data to ensure uniform replicate variance across the range of expression intensities [27].

Probabilistic Model for Identification of Periodic Expression Changes

To identify genes with periodic expression patterns across multiple hair growth cycles, we construct a two-component probabilistic model with periodic and background components. The model includes binary indicators of periodicity that select one of the two mixture components for each of the probe sets. We use Bayesian inference techniques to estimate whether the observed data for each of the probe sets is more consistent with periodic or background expression, resulting in the final ranking of probe set with respect to the posterior probability of periodicity (see Text S1). Periodic component of the model is shown in Figure 1C using the framework of directed graphical models and plate notation [48]. Nodes within the plate (outermost rectangle labeled “n”) correspond to a single probe set. The plate indicates that these nodes are repeated for each of the probe sets and they share a dependence on a set of common periodic profiles and other parameters \( \Phi \). Circular nodes are continuous variables; square nodes are binary indicators. Large shaded rectangles visually group variables for each of the individual cycles. For each probe set, the hypothetical ideal cycle profile (light blue nodes) is chosen from a mixture of possible profiles. Individual cycles (blue nodes) follow the corresponding time points of the ideal cycle, but the model allows for three types of systematic differences between the cycles. First, expression measured on different generations of the Affymetrix platform may differ by some probe set-specific additive offset (light green node). Second, involvement in the initial hair follicle morphogenesis for some probe sets (light orange node) may cause altered expression during the first two time points of the first cycle. Third, involvement of some other probe sets in injury response to depilation (another light orange node) may cause altered expression during the first two time points of the third cycle. Actual replicates (red nodes) are conditionally independent observations of the individual cycles with probe set-specific replicate variance (green nodes). Finally, only the red nodes in the model are observed. Parameters of the priors \( \Phi \) are estimated from the data using empirical Bayes framework. Bayesian inference techniques are used to marginalize over all other latent nodes in order to infer the posterior probability of periodic expression for each of the probe sets, conditioned on the observed replicate data and the prior parameters.

Determination of Gene Expression Changes Due to Tissue Composition Changes

Previous studies have shown that the thickness of different layers of skin (epidermis, dermis, subcutaneous adipose tissue, and hair follicle depth) is significantly altered during the hair growth cycle [3,49]. Genes whose expression in skin changes simply due to differences in the tissue composition of skin during the hair growth cycle are less likely to play regulatory roles than genes that are regulated within cells. Hence, we used a computational approach to systematically distinguish these two types of differential expression. To identify gene expression changes that are solely caused by tissue composition change over the hair growth cycle, we built a two-component Gaussian mixture model, where one component captures the expression profiles for a set of marker genes that are due to tissue composition change and the other component captures the background. The profiles for the following marker genes of different cell types were used: filaggrin (probe set ID 1427268_at) and keratin 1 (1420183_at) for the cornified cells; keratin 1 (1422481_at) and keratin 10 (1452166_at) for the suprabasal cells; vimentin (1450641_at) and S100a4 (1424542_at) for mesenchymal cells; Mef2a (1452347_at), Mef2c (1421027_a_at), and desmin (1426731_at) for myocytes. Their profiles all display a characteristic U-shaped pattern during the hair growth cycle, reflecting that these cell types make up a smaller percentage of total skin tissue during anagen compared to telogen. Other genes that are expressed in these cell types would display similar profiles to these marker genes, so the mixture model was applied to the 8433 periodically expressed probe sets. Using this mixture model, we found that 2040 probe sets have high posterior probabilities (>0.9) of periodic gene expression changes due to tissue composition change over the hair growth cycle. Excluding these probe sets results in 6393 probe sets that we define as hair cycle-regulated genes.

Statistical Differential Expression Analysis

Hair cycle-regulated expression profiles of the second synchronized cycle were used for statistical differential expression analysis because it is not perturbed by processes such as morphogenesis and wound healing that occur during the first and depilation-induced hair growth cycles, respectively. The time points for second hair growth cycle are classified into different phases of the hair growth cycle based on established morphological guidelines [3] as follow: early anagen (P23, P25), mid anagen (P27), late anagen (P29), early catagen (P37, P39), mid catagen (P41), telogen (P41), and wound healing that occur during the first and depilation-induced hair growth cycles, respectively. The time points for second hair growth cycle are classified into different phases of the hair growth cycle based on established morphological guidelines [3] as follow: early anagen (P23, P25), mid anagen (P27), late anagen (P29), early catagen (P37, P39), mid catagen (P41), telogen (P41). One-way ANOVA was performed on the TCM-transformed values of samples from a particular phase of the cycle to samples from the previous phase to determine upregulated genes (P<0.01). Significant enrichment of GO Biological Process categories within the different sets of genes upregulated at specific phases of the cycle was determined using DAVID functional annotation analysis [50]. Transcriptional regulators were systematically identified from the list of hair cycle-regulated genes by searching for the annotation category “regulation of transcription” in the GO Biological Process annotations. Using Partek Genomics Suite, partitioning cluster analysis with Euclidean distance was performed to group the second hair growth cycle TCM-transformed profiles of the transcriptional regulators.

Quantitative Real-Time PCR

For cDNA synthesis of RNA (1 mg as input) extracted from dorsal skin, High Capacity cDNA Reverse Transcription Kit (Applied Biosystems) was performed as described [27]. For cDNA synthesis of RNA isolated from LCM samples, Sensiscript RT Kit (Qiagen) was performed following manufacturer’s protocol. The following TaqMan Gene Expression Assays (Applied Biosystems) were used. For circadian-regulated genes: Bmal1 (Mm00453594_m1), Clock (Mm00433426_m1), Cyp2a10 (Mm00453594_m1), Ddb1 (Mm00119021_m1), Nr1d1 (Mm000520708_m1), Per2 (Mm01285621_m1), and Rorc (Mm0126119_g1). For cell cycle-related genes: Ccnd1 (Mm00432059_m1), Ccnb1 (Mm00052840_m1), Cdk4a1a
Wild cell lysates from telogen (P20) and late anagen (P30) mouse dorsal skin were collected at ZT16. The following primary antibodies were used for overnight incubation: rabbit anti-mouse PER2 (Affinity Bioreagents, 1:500 dilution) and rabbit anti-mouse GAPDH (Ambion, 1:1000 dilution). Secondary antibody used was peroxidase-conjugated affinity pure goat anti-rabbit polyclonal antibody (Jackson ImmunoResearch, 1:10000 dilution).

Circadian Experiments

Two groups of C57BL/6 mice (104 mice total) were used for circadian experiments: P30 (late anagen; anagen IV to VI) and P46 (telogen). These two time points were selected because the follicles stay in late anagen and telogen phases for several consecutive days (verified with histological sections). Prior and during the experiments, the mice were carefully housed under alternating 12 hours light/dark cycles. For each group, four mice were sacrificed every four hours over the course of 48 hours, and total RNA was extracted from the same upper-mid region of dorsal skin as well as the liver for control. Similar circadian Dhp expression levels were found for liver taken from P30 and P46 mice.

Laser Capture Microdissection

The excised dorsal skin was immediately embedded in O.C.T. Compound (Sakura Finetek USA, Torrance, CA), frozen in dry ice and stored at \(-80^\circ\)C. Serial cryostat sections (8 \(\mu\)m thickness) were cut and mounted on autoclaved polytarthalene (PET) foil stretched on a metal frame (Leica). Tissue was fixed in cold acetone for 2 min and stained using Arcturus HistoGene LCM Frozen Section Staining Kit (Arcturus, Mountain View, CA) according to manufacturer’s protocol. PET foil metal frames were mounted on a Leica AS LMD system (Leica) with the section facing downwards. Laser and microscope settings were as follow: 150x objective, aperture 6, intensity 46. The pulsed UV laser beam was carefully directed along the borders of each of the structures: whole hair follicles, epidermis, and dermis. Cross-contamination is very minimal in LCM samples as verified by Q-real-time PCR of the following specific markers: whole hair follicles, epidermis, and dermis. Cross-contamination is very minimal in LCM samples as verified by Q-real-time PCR of the following specific markers: whole hair follicles, epidermis, and dermis.

Western Blotting

Whole cell lysates from telogen (P20) and late anagen (P30) mouse dorsal skin were collected at ZT16. The following primary antibodies were used for overnight incubation: rabbit anti-mouse PER2 (Affinity Bioreagents, 1:500 dilution) and rabbit anti-mouse GAPDH (Ambion, 1:1000 dilution). Secondary antibody used was peroxidase-conjugated affinity pure goat anti-rabbit polyclonal antibody (Jackson ImmunoResearch, 1:10000 dilution).

Quantitative Hair Cycle Histomorphometric Analysis

Analysis was performed as previously described with minor modifications [32].

Expression Profiling of Dorsal Skin from Bmal1\(^{-/-}\) Mice

Histological sections were used to verify that the hair follicles are in the first synchronized telogen based on established morphological guidelines [3]. RNA extraction from dorsal skin, clean-up, and array hybridization were the same as that described for the time-course microarrays above. We profiled three Bmal1\(^{-/-}\) and three Bmal1\(^{+/+}\) littermates, with each sample separately hybridized to an array (Alfametrix Mouse Gene 1.0 ST array). Statistical analyses were performed using Cyber-T program [53]. The cutoff for significant differential expression is set at F-value of 0.001, which corresponds to a false discovery rate of within 7% based on the calculated posterior probability of differential expression. The wild-type and Bmal1\(^{-/-}\) mutant microarray datasets are deposited in the NCBI Gene Expression Omnibus (www.ncbi.nlm.nih.gov/geo, GSE14006).

Immunohistochemistry

Dorsal skin was fixed in 10% formalin, paraffin-embedded and sectioned at 6-\(\mu\)m. Antigen-retrieval was performed by heating slides in 0.01 M citrate buffer (pH6) for 20 min using an autoclave oven. After quenching endogenous peroxidase activity with 3% hydrogen peroxide for 5 min, sections were permeabilized using 0.2% Triton-X for 5 min. We then applied DakoCytomation Protein Block Serum-Free (Dako) to the sections for 30 min. Next, the slides are incubated overnight at 4\(^{\circ}\)C with the following primary antibodies: phospho-histone H3 (Upstate, 1:1000), phospho-Rb Ser807/811 (Cell Signaling, 1:100), Keratin 5 (Covance, 1:1000), AE13 and AE15 (kindly provided by Dr. T. T. Sun, 1:1000). We applied 1:500 biotinylated IgG secondary antibodies (Vector) for 1 hr, and then incubated in Vectastain elite ABC Reagent (Vector) for 30 min. The slides were stained using the DakoCytomation Liquid DAB+ Substrate Chromogen System (Dako), and counterstained using 1:5 diluted hematoxylin followed by bluing reagent.

Supporting Information

Figure S1 Exclusion of gene expression changes that correspond to tissue composition changes. (A) Expression profiles of marker genes that are altered as the tissue composition changes during the hair growth cycle. The marker genes for the different cell types are as follows: filaggrin and loricrin for the cornified cells, keratin 1...
and 10 for the suprabasal cells, vimentin and S100a4 for mesenchymal cells, and Mef2a, 2c, and desmin for myocytes. (B) Mixture model identified genes that can be explained by tissue composition changes over the hair growth cycle. The x-axis is the posterior probability of gene expression changes due to tissue composition changes, and the y-axis is the number of probe sets within each range of posterior probabilities.

**Figure S3** Expression of circadian clock genes and proteins in mouse dorsal skin at different phases of the hair growth cycle. (A) In situ hybridization staining of telogen, early anagen, late anagen, and catagen dorsal skin at ZT10 with *Bmal1* (left column) and *Dbp* (right column) anti-sense probes. Note the black pigment of the hair shaft in late anagen hair follicles is not hybridization signal. (B) As negative control, in *situ* hybridization staining of telogen, early anagen, and late anagen dorsal skin at ZT10 with *Dbp* sense probes. Dashed lines indicate border between epidermis and dermis. Brackets indicate the different layers of the skin: E - epidermis, D - dermis, SC - subcutaneous adipose layer. Bu - bulge, CH - club hair, DP - dermal papilla, HB - hair bulb, HS - hair shaft, IRS - inner root sheath, Mx - matrix, ORS - outer root sheath, SHG - secondary hair germ, SG - sebaceous gland. (C) Levels of PER2 proteins are not significantly different between telogen (P20) and late anagen (P30). Shown are two independent whole cell lysates from mouse dorsal skin collected at ZT16.

Found at: doi:10.1371/journal.pgen.1000573.s003 (0.75 MB PDF)

**Figure S4** Expression of circadian clock genes from laser capture microdissected skin compartments. Q-PCR of *Bmal1* (A), *Per2* (B) and *Cry2* (C) from LCM-hair follicles, dermis, and epidermis for telogen and late anagen dorsal skin at ZT10 and ZT18/ZT2. (D) Q-PCR of *Dbp* from laser capture microdissected hair follicles at telogen, early anagen (anagen I-II), mid anagen (anagen III), late anagen (anagen IV-VI). For all panels, standard deviations were determined by using three replicates normalized to *Gapdh*. Ct values indicate detectable expression of clock genes in every sample, and fold was calculated relative to the lowest expression sample.

Found at: doi:10.1371/journal.pgen.1000573.s004 (0.06 MB PDF)

**Figure S5** No morphological abnormalities in skin and hair follicle in *Clock* and *Bmal1* mutant mice. (A) Hair follicle structures are normal in *Clock* and *Bmal1* mutant mice. The top row show the H&E sections of hair follicles in dorsal skin of *Clock* and *Bmal1* mutant mice and their control littermates at late anagen. The bottom three rows are the corresponding immunostainings of the following specific hair differentiation markers: AE13 (cortex and cuticle of the hair shaft), AE15 (inner root sheath and medulla of the hair shaft), K5 (outer root sheath). Note that this particular *Bmal1*+/− mouse has white fur coat and therefore the unpigmented hair shaft reveals expected AE15 staining in the medulla. (B) No difference in the thickness of the subcutaneous adipose layer of *Bmal1*+/− and control dorsal skin. Note we measured thickness for comparable stages of hair follicle cycling: *Bmal1*+/− mice reaches late anagen at P34-P35, and *Bmal1*−/− and *Bmal1*+/− mice reaches late anagen at P39-P31.

**Table S1** Time-course profile clustering of hair-cycle regulated genes. Probe set ID corresponds to the array used for the second and depilation-induced hair growth cycles (Mouse Genome 430 2.0). Old probe set ID corresponds to the array used for the first hair growth cycle (Murine Genome U74Av2). Columns labeled 1–9 correspond to log-transformed, zero-mean gene expression profiles for the “ideal hair cycle.”

Found at: doi:10.1371/journal.pgen.1000573.s006 (2.04 MB XLS)

**Table S2** List of genes previously reported to have hair cycle-dependent gene expression changes. Probe set ID corresponds to the array used for the second and depilation-induced hair growth cycles (Mouse Genome 430 2.0). Old probe set ID corresponds to the array used for the first hair growth cycle (Murine Genome U74Av2). pHC is the posterior probability of being periodically expressed during the hair growth cycle. Note some genes have multiple probe sets, which have different hybridization signals and thus result in differences in pHC values.

Found at: doi:10.1371/journal.pgen.1000573.s007 (0.08 MB PDF)

**Table S3** Hair cycle staging of *Bmal1* knockout mouse (+/−) and their control littermates (+/+ and +/+). For each postnatal day (P), mice are grouped by genotype and each mouse is classified into specific phases/stages of the hair growth cycle based on the majority of hair follicles using established morphological guidelines. In general, we noted a slightly more advanced hair cycle progression in male mice; the table includes both genders which accounts for most of the variation within each genotype, but does not explain the observed differences between genotypes. Hence, for hair cycling progression comparison across genotypes, we matched littermates by gender.
