*Candida albicans* is a major fungal pathogen in humans. In *C. albicans*, secreted aspartyl protease 2 (Sap2) is the most highly expressed secreted aspartic protease in *vitro* and is a virulence factor. Recent research links the small GTPase Rhb1 to *C. albicans* target of rapamycin (TOR) signaling in response to nitrogen availability. The results of this study show that Rhb1 is related to cell growth through the control of Sap2 expression when protein is the major nitrogen source. This process involves various components of the TOR signaling pathway, including Tor1 kinase and its downstream effectors. TOR signaling not only controls Sap2 transcription but also affects Sap2 protein levels, possibly through general amino acid control. DNA microarray analysis identifies other target genes downstream of Rhb1 in addition to Sap2. These findings provide new insight into nutrients, Rhb1-TOR signaling, and expression of *C. albicans* virulence factor.

*C. albicans* is a major opportunistic fungal pathogen in humans, and it inhabits the skin and mucosal surfaces of healthy people (12). In immunocompromised patients such as those undergoing organ transplantation or chemotherapy or those with AIDS, *C. albicans* is responsible for a number of life-threatening infections with considerable morbidity and mortality (54). Several virulence factors contribute to *C. albicans* infection, including the expression of adhesins, yeast-to-hypha morphogenesis, phenotypic switching, and secreted hydrolytic activities (13).

Secreted aspartyl proteases (Saps) encoded by 10 members of the SAP gene family, SAP1 to SAP10 (50), are among the hydrolytic factors of *C. albicans* virulence. These genes are differentially expressed during various stages of *C. albicans*-host interaction, and each Sap protein possesses unique enzymatic characteristics and substrate specificities (50). Sap2 is the most highly expressed secreted protease in *vitro* and is capable of digesting human albumin, hemoglobin, keratin, and secreted immunoglobulin A (33). Sap2 is believed to allow *C. albicans* to destroy host barriers through the degradation of human proteins, followed by deep penetration into tissues or the bloodstream. In addition, Sap2 digests extracellular proteins into oligopeptides that can be taken up by oligopeptide transporters encoded by the OPT gene family (59). Therefore, Sap2 may also be critical for cell growth in the human host and may enable the use of host proteins as a nitrogen source. A *C. albicans* strain that lacks SAP2 loses its virulence in a murine model of infection (34). However, using URA3 as a marker during the construction of *C. albicans* mutants can make it difficult to interpret the resulting phenotypes (4, 11, 16, 37, 65). When URA3 assessment is eliminated from strain construction, Sap1 to Sap6 do not seem to be required for *C. albicans* invasion into reconstituted human epithelia (39). Sap1 to Sap6 played limited roles in *C. albicans* virulence and the host immune response in a murine model of disseminated infection (17). These studies showed that the roles of Sap2 and other Sap proteins in *vitro* still need to be clarified.

In fungi, the target of rapamycin (TOR) signaling pathway plays a key role in controlling different cellular processes in response to multiple environmental cues, including nutrient availability and stress (55, 61). The central component of this pathway is Tor, a serine/threonine protein kinase. *Saccharomyces cerevisiae* contains 2 TOR genes encoding 2 closely related kinases, Tor1 and Tor2. In association with a subset of proteins, including Kog1, Lst8, and Tco89, Tor1 or Tor2 forms TOR complex 1 (TORC1) (15, 41, 58, 79). Tor2 can also associate with another subset of proteins (e.g., Avo1, Avo2, Lst8, and Bit2) to form TOR complex 2 (TORC2) (24, 41, 58, 79). Although TORC1 and TORC2 share some functions, each complex controls distinct cell processes in response to environmental signals (41, 61).

In *S. cerevisiae*, TORC1 is rapamycin sensitive (61). Genetic analysis reveals that TORC1 functionally interacts with genes involved in actin polarization and membrane trafficking (2). TORC1 is also involved in nitrogen catabolite repression (NCR) through its regulation of 2 GATA-type transcriptional factors, Gat1 and Gln3 (7, 9, 18, 27, 35, 45, 46, 61, 62). In the presence of good nitrogen sources, Gln3 and Gat1 are restricted to the cytosol, leading to inactivation of the NCR genes. Similar expression patterns of NCR genes during nitrogen deprivation also appear in cells treated with rapamycin (14). The TORC2 protein complex regulates the polarization of the actin cytoskeleton in a rapamycin-insensitive manner (41). TORC2 is also involved in controlling cell wall integrity and receptor endocytosis (23). In the fission yeast *Schizosaccharomyces pombe*, loss of Tor2 function activates genes that are also induced during nitrogen starvation (49). Only 1 TOR gene, TOR1, has been identified in *C. albicans* (20). A recent study suggests that the *C. albicans* Tor1 kinase is involved in cell-cell adhesion and biofilm formation in nutrient-poor Spider medium but not under other tested conditions (6). Cell adhesion and biofilm formation are mediated by controlling the expression of the adhesin genes ALS1, ALS3, and HWP1 through Tor1 (6).
C. albicans, Gln3 and Gat1 are also regulate nitrogen metabolism and may function downstream of Tor1 kinase (40).

Recent research links the small GTPase Rhb1 to TOR signaling in C. albicans (72). Rhb1 was first identified in mammals and functions as a positive regulator of mammalian Tor (mTOR) kinases (42). In humans, GTP binding activates the homolog of C. albicans Rhb1 (named Rhgb), and Rhgb-GTP in turn stimulates the kinase activity of mammalian TORC1 (mTORC1) to trigger downstream signaling cascades (42). In fission yeast, rhb1-null mutants show arrested cell growth and division with a terminal phenotype similar to that caused by nitrogen starvation (44). Rhb1 deletion depletes the expression of fnx1 and mei2*, which are normally induced by nitrogen starvation (44). In C. albicans, Rhb1-TOR is involved in nitrogen starvation-induced morphogenesis, likely by controlling the expression of MEP2 (72). MEP2 is a permease and ammonium sensor (10, 21). The expression of MEP2 is upregulated in nitrogen-limited conditions and is controlled by C. albicans Gln3 and Gat1 (21). In addition, gln3 and gat1 deletion mutants exhibit reduced sensitivity to rapamycin (40), suggesting that these transcriptional regulators may also be involved in TOR signaling in C. albicans. In the presence of protein and low nitrogen availability, Gln3 and Gat1 control the expression of SAP2 by regulating the Stp1 transcription factor (22). These studies suggested that Rhb1 and Tor1 kinase may also be related to SAP2 expression.

This study investigated the roles of Rhb1 and TOR signaling in SAP2 expression. In addition to SAP2, other target genes of Rhb1 were identified using DNA microarray analysis. The results highlighted an important link between protein utilization and Rhb1-TOR signaling in C. albicans.

MATERIALS AND METHODS

Strains and growth conditions. Table 1 lists the C. albicans strains used in this study. All strains were routinely grown at 30°C in YPD medium (10 g/liter yeast extract, 20 g/liter peptone, 20 g/liter glucose) and synthetic defined (SD) medium (6.7 g/liter yeast nitrogen base without amino acids, 20 g/liter glucose, 0.79 g/liter complete supplement mixture [CSM] of amino acids; MP Biochemicals, Solon, OH). To determine cell growth and the expression levels of SAP2 and its gene product, a single colony from each strain was grown overnight at 30°C in YPD medium, washed, and subcultured at an optical density at 600 nm (OD600) of approximately 0.5 in YCB-BSA-YE (0.01% or 0.05% or 0.01% or 0.05% or 0.01% yeast carbon base, 4 g/liter bovine serum albumin [BSA], 0.01 g/liter or 0.05 g/liter yeast extract, adjusted to pH 4.4 with HCl) (19) and subsequently grown at 30°C for different times.

Cells were grown in SD medium overnight to determine the effect of rapamycin on SAP2 expression. The overnight culture was diluted in fresh SD medium to an OD600 of 0.5. Each culture was then incubated at 30°C to reach mid-log phase (30°C, 3.5) and divided into 6 individual tubes. Three of the tubes contained 0.2 μg/ml rapamycin (from a 100 μg/ml stock dissolved in methanol), and the others contained equal volumes of methanol (vehicle control [VC]). Cells were incubated at 30°C for 30, 60, or 120 min and collected by centrifugation for RNA preparation.

CFU counting. To determine the cell numbers of each strain grown in YCB-BSA-YE (0.01% medium), the CFU were counted after various incubation periods. Sterile phosphate-buffered saline (PBS) buffer was used for the serial dilution of the cells. Each cell was placed on ice before being plated onto YPD agar plates. CFU were counted after incubation at 30°C for 36 h.

Plasmid and strain constructions. The SAT1 flipper method (60) was used to generate the C. albicans STP1 null mutant. The primers used in this study are listed in Table S3 in the supplemental material. A 420-bp Apal-Xhol DNA fragment carrying the upstream flanking sequence of STP1 was obtained from the C. albicans SC5314 genome with PCR amplification using primers CaSTP1-5'-1 and CaSTP1-3'-2. A 416-bp SacI-Sali DNA fragment containing the downstream flanking sequence of STP1 was similarly amplified using primers CaSTP1-3'-1 and CaSTP1-3'-2. Both fragments were independently digested and cloned into the pSF92A plasmid (60) to generate the pSF92dSTP1 plasmid. The DNA fragment carrying the flanking regions of STP1 and the SAT1 flipper cassette was isolated from pSF92dSTP1 by digestion with Apal and Sac1. This fragment was purified and transformed into the C. albicans SC5314 strain (60). Transformants were selected for nourseothricin resistance and resistant colonies were verified by PCR. To induce the MAL2-regulated excision of the SAT1-FLIP cassette, cells were grown overnight with shaking in YPM medium (10 g/liter yeast extract, 20 g/liter peptone, 20 g/liter maltose) and subsequently grown on YPM agar plates. The second round of deletion cassette integration and excision used a heterozygous mutant and yielded 2 independent homozygous stp1Δ constructs: CHIA-D1 and CHIA-D2. The SAT1 flipper method was also used to construct the RHBI deletion in the C. albicans JRB12 strain containing the rapamycin-resistant TOR1Δ allele (20). The Apal-Sacl DNA fragment containing 5' and 3' flanking regions of RHBI and the entire SAT1 flipper cassette was isolated from pSF92dRHBI1 (72). The DNA fragment was then transformed into JRB12 for integration into the RHBI locus by homologous recombination. Transformants were selected for nourseothricin resistance and grown for 3 days in YCB medium containing BSA (23.4 g/liter yeast base, 4 g/liter BSA, pH 4.0) to induce SAP2-regulated SAT1-FLIP cassette excision (60). The second round of gene deletion used C. albicans heterozygous RHBI mutants, yielding 2 independent constructs: JRB12RHBI1D1 and JRB12RHBI1D2.

LexA-Gat1 and Stp1-LexA fusions were constructed to test the transcriptional activity of Gat1 and Stp1 on the wild-type and rhb1-deleted backgrounds. Briefly, the DNA fragment containing the entire GAT1 gene was PCR amplified from the SC5314 genome by the use of primer pair CaGAT1-5' and CaGAT1-3'. The fragment was purified, digested with Mulu and Pst1, and cloned into the plasmid pcIplexA-F1 (31, 64) to generate pcIplexA-F-Gat1. The plasmid was linearized with StuI, and the fusion was introduced into the COP-LexAGat1, CCR-LexAGat1. Because the CAY1, PRT3, and SSV5 (SSP) sensor can proteolytically cleave the N terminus region of immature Stp1, LexA was fused to the C terminus of Stp1. The DNA fragment containing lexA with the Mulu and Pst1 restriction sites was amplified by PCR from the pcIplexA-F-Gat1 plasmid by the use of primer pair LexA and Mulu-F and primer pair PstA and Pst1-R. The fragment was purified, digested with Mulu and Pst1, and cloned into pcIplexA-F-Gat1 to replace Gat1 and generate the plasmid pcIplexA-F-LexA. The DNA fragment containing the entire STP1 gene was PCR amplified from the SC5314 genome by the use of primer pair CaSTP1-5'-3 and CaSTP1-3'-3. This DNA fragment was purified, digested with HindIII and Mulu, and cloned into pcIplexA-F-LexA. The fragment replaced the region downstream of lexA, generating pcIplexStp1-LexA. The plasmid was then linearized with Stul, and the STP1-lexA fusion was introduced into the RPS1 locus in COP1 and CCR1 strains to generate COP-LexAgat1, CCR-LexAgat1, COP-Stp1LexA, and CCR-Stp1LexA strains as described above, yielding RHBI1DCOP-LexAgat1, RHBI1DCR-LexAgat1, RHBI1DCOP-Stp1LexA, and RHBI1DCR-Stp1-LexA, respectively (Table 1). To overexpress RHBI1 in COP-LexAgat1, CCR-LexAgat1, COP-Stp1LexA, and CCR-Stp1LexA strains as described above, yielding RHBI1DCOP-LexAgat1, RHBI1DCR-LexAgat1, RHBI1DCOP-Stp1LexA, and RHBI1DCR-Stp1-LexA, respectively (Table 1). To overexpress RHBI1 in COP-LexAgat1, CCR-LexAgat1, COP-Stp1LexA, and CCR-Stp1LexA strains as described above, yielding RHBI1DCOP-LexAgat1, RHBI1DCR-LexAgat1, RHBI1DCOP-Stp1LexA, and RHBI1DCR-Stp1-LexA, respectively (Table 1). To overexpress RHBI1 in COP-LexAgat1, CCR-LexAgat1, COP-Stp1LexA, and CCR-Stp1LexA strains as described above, yielding RHBI1DCOP-LexAgat1, RHBI1DCR-LexAgat1, RHBI1DCOP-Stp1LexA, and RHBI1DCR-Stp1-LexA, respectively (Table 1). To overexpress RHBI1 in COP-LexAgat1, CCR-LexAgat1, COP-Stp1LexA, and CCR-Stp1LexA strains as described above, yielding RHBI1DCOP-LexAgat1, RHBI1DCR-LexAgat1, RHBI1DCOP-Stp1LexA, and RHBI1DCR-Stp1-LexA, respectively (Table 1).
TABLE 1 C. albicans strains used in this study

| Strain | Parent strain | Genotype or characteristic(s) | Reference |
|--------|---------------|--------------------------------|-----------|
| SC5314 | Wild type     |                                | 26        |

**RHB1 mutants**
- CCT-D1 : SC5314  
- CCT-D2 : SC5314  
- CCT-RD1 : CCT-D1  
- CCT-OE1 : SC5314  
- CCT-OE2 : SC5314

**GLN3, GAT1, STP1 mutants**
- GLN3M4A : GLN3M3A  
- GLN3M4B : GLN3M3B  
- GAT1M4A : GAT1M3A  
- GAT1M4B : GAT1M3A  
- Δgln3GAT1M4A : Δgln3GAT1M3A  
- Δgln3GAT1M4B : Δgln3GAT1M3B  
- STP1M4A : STP1M3A  
- CHA-D1 : SC5314  
- CHA-D2 : SC5314

**TOR1-FRB mutant**
- JRB12 : SC5314

**TOR1-FRB RHB1 double mutants**
- JRB12RHB1D1 : JRB12  
- JRB12RHB1D2

**SAP2 mutants**
- SAP2M5A : SAP2M5A  
- SAP2ex4A : SAP2M5A  
- TetGFP-1 : SC5314

Yeast one-hybrid assay
- COP1 : CAI8  
- CCR1 : CAI8  
- OC1 : COP1  
- CC1 : CCR1  
- OG21 : COP1  
- CG21 : CCR1  
- COP-Strp1LexA : COP1

- OERHB1CCR-LexAgat1 : CCR-LexAgat1

SacII and KpnI digestion. The fragment was then transformed into 1 allele of the ADH1 locus of SC5314 to generate TetGFP.

RNA isolation, reverse transcription-PCR (RT-PCR), and real-time quantitative PCR. Total RNA isolation and cDNA synthesis were performed as described previously (72). For PCRs, 1 µl of cDNA served as the template for 1 cycle of 94°C for 10 min, followed by different numbers of cycles of 94°C for 30 s and 56 to 60°C for 30 s as indicated and 1 cycle of 72°C for 5 min. The PCR products were analyzed on 1.2% agarose gels and visualized by staining with SYBR Safe (Invitrogen, Carlsbad, CA).

Quantitative PCR was performed using MicroAMP optical 96-well reaction plates (catalog no. N801-0560; Applied Biosystems, Framingham, MA) and MicroAMP optical adhesive film (catalog no. 4311971; Applied Biosystems), the SYBR green-based detection assay, and a 7500 real-time PCR system (Applied Biosystems). Each 20-µl reaction mixture consisted of 1 µl of cDNA, 0.3 µl of 20 µM of sense and anti-sense primers, 8.4 µl of water, and 10 µl of Power SYBR green PCR Master Mix (catalog no. 4367659; Applied Biosystems). The reaction conditions were 1 cycle of 50°C for 2 min and 95°C for 10 min, followed by 40 cycles of 95°C for 15 s and 60°C for 1 min. Each sample was amplified in triplicate, and each experiment was performed 3 times. Data analysis was performed with

Chen et al.

SacII and KpnI digestion. The fragment was then transformed into 1 allele of the ADH1 locus of SC5314 to generate TetGFP.
Real-Time PCR System Sequence Detection software version 1.4 (Applied Biosystems). An average threshold cycle (C_{T}) value was obtained and normalized to the average C_{T} value of EF1B1. The comparative C_{T} method was used to quantify gene expression, and the relative expression was determined to be 2^{-ΔΔC_{T}} (36).

Protein preparation and Western blotting. Whole-protein lysate was prepared by suspending cells in 1% Nonidet P-40 (NP-40) extraction buffer (50 mM NaH₂PO₄ [pH 8.0], 150 mM NaCl, 1% NP-40) containing a 100-fold-diluted protease inhibitor cocktail (catalog no. P-8215; Sigma-Aldrich, St. Louis, MO) and 200 mM phenylmethylsulfonyl fluoride. Cells were broken using a vortex procedure with acid-washed glass beads for 30 s and immediately placed on ice for 30 s. This step was repeated 10 times. Soluble proteins were collected by centrifugation (13,300 x g) for 10 min at 4°C and quantified with a bichinonic acid (BCA) protein assay kit (Pierce, Rockford, IL). To detect secreted Sap2 and BSA in the medium, 20 μl of the supernatant was loaded onto a 12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gel, and proteins were visualized with Coomassie blue staining. For Western blot analysis, proteins were subjected to 12% SDS-PAGE and transferred onto polyvinylidene difluoride membranes (Pall, Port Washington, NY) by the use of Towbin transfer buffer (24 mM Tris base, 192 mM glycine, 20% methanol) and a TE77 semidry transfer unit (GE Healthcare Bio-Sciences, Piscataway, NJ). Sap2 was detected with mouse monoclonal anti-Sap2 (catalog no. M1666; Takara Bio, Shiga, Japan) (1:2,000 dilution). GFP was detected with JL-8 anti-GFP mouse monoclonal antibody (catalog no. 623280; Clontech, Palo Alto, CA) (1:2,000 dilution), and horseradish peroxidase (HRP)-conjugated goat anti-mouse IgG (Santa Cruz Biotechnology, Santa Cruz, CA) (1:10,000 dilution) was used as the secondary antibody. The chemiluminescence (ECL) was detected with Western Lighting Plus ECL reagents (Perkin-Elmer, Waltham, MA) and exposed to X-ray films (Fujifilm, Tokyo, Japan).

One-hybrid assay. A one-hybrid assay was performed as described previously (64). Briefly, cells were grown overnight in YPD broth at 30°C, washed, subcultured in fresh YCB–BSA–0.01% YE medium, and grown for 3.5 h to reach mid-log phase. The supernatant was removed by centrifugation (1,500 x g), and the cell pellets were suspended in Z buffer (50 mM NaH₂PO₄, pH 6.7, 150 mM NaCl, 0.5% [wt/vol] NP-40, 1 mM MgSO₄, 7% [vol/vol] glycerol, and 10 μg/ml CHX) (pH 7.0). Cells were then lysed by adding 15 μl of 0.1% SDS and 30 μl of chloroform and vortexing for 15 s. The suspensions were incubated for 30 min at 37°C in 0.2 ml of potassium phosphate buffer (pH 7.0) containing 4 mg of o-nitrophenyl-β-D-galactopyranoside/ml. The reactions were terminated with 0.4 ml of 1 M Na₂CO₃ when the suspension turned yellow. The supernatants from the two reactions were then collected by centrifugation. The cell pellets were washed and resuspended in sterile water to approximately 5 x 10⁶ cells/ml. The resulting cell suspension (5 μl) was spotted onto YCB–BSA–YE (pH 7.0) plates (plates with 1.5% agar) containing 0.01 mg/ml rapamycin. The size of the clear zone surrounding the cells was measured after incubation at 37°C for 4 days.

DNA microarray fabrication and sample preparation. An Operon 70-mer probe set (Array-Ready Oligo Sets; AROS V1.2), containing 6,266 probes, and the C. albicans AROS upgrade set (V1.1), containing 1,659 probes, was used to construct DNA microarrays. These 70-mer oligonucleotide sets contain 7,923 optimized probes that represent the entire genome of C. albicans and more than 10 different controls. These oligonucleotide sets have been successfully used in studies on C. albicans biology and pathogenesis (1, 6, 84). The probes were resuspended in 3 x SSC buffer (1 x SSC is 0.15 M NaCl plus 0.015 M sodium citrate) to a final concentration of 40 μM.

The printing of the C. albicans microarrays was carried out at the DNA Microarray Core Laboratory of the Institute of Plant and Microbial Biology, Academia Sinica, Taiwan. The oligonucleotides were spotted onto UltraGAPS coated slides (Corning, New York, NY) using an OmniGrid 100 microarrayer (Genomic Solutions, Ann Arbor, MI). The 1st, 50th, and 100th chip of each batch (100 chips per batch) were selected and scanned with an Axon GenePix 4000B array scanner (Axon Instruments, Inc., Union City, CA) to ensure the quality of the microarray printing. The quality of the test microarrays was determined visually.

For DNA microarray analysis, a single colony of either the SC5314 (wild-type) strain or the CCT-D1 (rhb1-deleted) strain was inoculated into SD medium and grown overnight at 30°C. These cultures were then subcultured in 40 ml of SD medium and grown at 30°C for 5.5 hours until they reached the mid-log phase (OD₆₀₀ ~ 3.5). The cells were then collected by centrifugation. Total RNA was extracted with an RNeasy kit (catalog no. 74106; Qiagen, Valencia, CA) and treated with Turbo DNA-free DNase (Ambion, Austin, TX) at 37°C for 1 h. After purification, the quality and quantity of total RNA were determined using a model 2100 Bioanalyzer (Agilent Technologies, Santa Clara, CA) or agarose gel electrophoresis and an ND-1000 spectrophotometer (NanoDrop Technologies). cDNA synthesis, aRNA synthesis, and Cy dye coupling were conducted using an Amino Alkyl MessageAmp II aRNA amplification kit (catalog no.

RESULTS
Rhb1 regulates cell growth in the presence of BSA by controlling Sap2 expression. Sap2 is the major secreted protease of C. albicans in vitro (32, 81). Sap2 expression is induced in medium in which protein is the nitrogen source and is repressed in the presence of a more favorable nitrogen source, such as ammonium (22). Previous research showed that Rhb1 is involved in filamentation mediated by nitrogen starvation (72). This implies that Rhb1 may play a role in cell growth in medium where protein is the major source of nitrogen. To test this hypothesis, C. albicans cells were grown in yeast carbon base (YCB) medium supplemented with bovine serum albumin (BSA) (as the nitrogen source) and a limited amount (0.01%) of yeast extract (YE) to reduce overall incubation time (22). Figure 1A depicts the growth rate of C. albicans. The rhb1-deleted strain showed a growth rate similar to those of the wild-type and RHBI-reconstituted strains. Cells in which RHBI expression was driven by the ADH1 promoter and RHBI was overexpressed (72) grew slower than wild-type cells. However, cells overexpressing RHBI exhibited an optical density similar to that of the wild type after prolonged incubation (Fig. 1A). The sap2-deleted mutant was used as a control, as it did not grow in YCB–BSA–YE (0.01%) medium (Fig. 1A) (21). The numbers of CFU were also counted (see Fig. S1 in the supplemental material) to avoid cell size or morphology variations that might have led to inaccurate OD600 data for Fig. 1A. The pattern of cell growth derived from CFU counting was similar to that represented in Fig. 1A. However, the slow growth of the strain overexpressing RHBI might have been caused by other nitrogen sources in the medium. The concentration of yeast extract in the medium was increased to 0.05% to avoid this possibility. This diminished the slow growth of the strain overexpressing RHBI (see Fig. S2 in the supplemental material) and largely restored the defect of the sap2-deleted strain (see Fig. S2 in the supplemental material). These results indicate that the slow growth of the strain overexpressing RHBI and the growth defect of sap2-deleted strain are related to BSA utilization.

To further correlate cell growth with BSA utilization, supernatants of cells grown in YCB–BSA–YE (0.01%) were analyzed with SDS-PAGE. After 24 h of incubation, BSA was completely digested by the wild-type, rhb1-deleted, and RHBI-reconstituted strains (Fig. 1B). However, 2 independent strains overexpressing RHBI showed lower BSA utilization efficiency. The strains overexpressing RHBI degraded BSA slowly after 10 h of incubation compared to the wild type (Fig. 1B), and the molecular weight of degraded protein was relatively high. Even after 24 h of incubation, peptides or low-molecular-weight proteins derived from BSA degradation were still apparent in the strains overexpressing RHBI (Fig. 1B). The low efficiency of BSA degradation seen with RHBI overexpression confirms the low growth rate of the same strain (Fig. 1A). The sap2-deleted mutant and a strain in which SAP2 is regulated by a tetracycline-inducible Ptet promoter (65) were used as controls. The sap2-deleted mutant slightly degraded BSA, and the degradation was substantially slower (Fig. 1B). However, protein degradation became apparent in the SAP2-reduced strain after the addition of doxycycline (a tetracycline antibiotic) (Fig. 1B). Western blotting using BSA antibody was performed to determine whether the lower-molecular-weight bands represented BSA or other proteins. The lower-molecular-weight bands were derived from BSA degradation (see Fig. S3 in the supplemental material). These results suggest that the protein utilization of the strain overexpressing RHBI is not as efficient as that of the other strains. Thus, the Rhb1 level may be correlated with the secretion or expression of secreted proteases.

Because Sap2 is the major secreted protease in vitro, the experiments in this study tested whether lower Sap2 expression levels result in delay of growth of the strain overexpressing RHBI. The expression of Sap2 was detected by Western blot analysis performed with Sap2 monoclonal antibody following previously described procedures (21). The rhb1-deleted mutant was the only mutant in which intracellular Sap2 was easily detected in cells after 12 h of incubation, as shown in Fig. 1C. The levels of extracellular Sap2 protein in other tested strains were too low to be detected. After 24 h of incubation, the expression levels of intracellular Sap2 seemed to reach saturation and were indistinguishable among the different samples. Nevertheless, the level of extracellular Sap2 in the strain overexpressing RHBI was much lower than in the others. The level of extracellular Sap2 in the rhb1-deleted strain was slightly higher than in the wild-type and RHBI-reconstituted
strain. After prolonged incubation (48 h), the level of the protein remaining in the medium was relatively low. Thus, Sap2 might not be required and was proteolyzed, further reducing the intracellular level of Sap2 compared to that seen in cells after 24 h of incubation. The different extracellular Sap2 levels among the strains were still apparent after 12 h but were almost indistinguishable after 24 h of incubation. Although the levels of Sap2 protein were higher in the \textit{rhb1} deleted mutant than in the wild type (Fig. 1C),

**FIG 1** Rhb1 regulates cell growth in medium with BSA as the major nitrogen source by controlling \textit{C. albicans} Sap2 expression. (A) Cells were grown in YPD broth overnight, washed twice with sterile water, and subcultured in YCB–BSA–YE (0.01%) medium (initial cell density, OD$_{600}$ = 0.5) at 30°C. The \textit{C. albicans} strains used in this experiment were SC5314 (wild type; filled triangles), CCT-D1 (\textit{rhb1} deleted; open squares), CCT-RD1 (\textit{RHB1} reconstituted; open circles), CCT-OE1 (overexpressing \textit{RHB1}; filled circles), and SAP2MS4A (\textit{sap2} deleted; filled squares). The doubling times for wild-type, \textit{rhb1} deleted, and \textit{RHB1} reconstituted strains were approximately 5.7 ± 0.2 h, 5.8 ± 0.02 h, and 5.7 ± 0.1 h, respectively. The doubling time for the strain overexpressing \textit{RHB1} in YCB–BSA–YE (0.01%) was approximately 6.1 ± 0.4 h. (B) BSA degradation by \textit{C. albicans} after 10 and 24 h of incubation. Each cell supernatant (20 μl) was analyzed by 12% SDS-PAGE, and proteins were visualized by Coomassie blue staining. Data represent the results of only 1 experiment, although experiments were performed at least 3 times with identical results. The rectangular box indicates peptides or low-molecular-weight proteins derived from BSA degradation. The arrow indicates the intact BSA (66 kDa). M, protein molecular marker; MW, molecular weight. (C) Expression of extracellular and intracellular Sap2 in different \textit{C. albicans} strains. Cells were grown as described in panel A for 12, 24, and 48 h, and Sap2 was detected by Western blotting. The nonspecific band served as the loading control and was used to normalize the intracellular Sap2 levels indicated by the fold change values. (D) Comparison of levels of cell growth on YPD and YCB–BSA–YE (0.01%) agar plates. Cells were grown overnight in YPD, washed, serially diluted 10-fold, and spotted onto agar plates. Plates were photographed after incubation at 30°C for 1 day. Data are representative of at least 3 independent experiments with identical results. Cell numbers are shown at the top of the panels.
the wild-type and rhl1-deleted strains showed similar growth rates in YCB–BSA–YE (0.01%) liquid medium (Fig. 1A). A possible explanation is that the rhl1-deleted mutant may exhibit a growth delay phenotype when growing in a nutrient-rich environment. To test this possibility, cells were grown in YPD-rich medium and compared to cells grown in a medium in which protein is the major nitrogen source. Equal numbers of cells were serially diluted and spotted onto YPD and YCB–BSA–YE (0.01%) agar plates. The rhl1-deleted mutant showed a slight delay in cell growth on YPD but not on YCB–BSA–YE (0.01%) agar plates (Fig. 1D). This suggests that high levels of Sap2 protein expression (Fig. 1B and C) may somehow compensate for the growth delay of the rhl1-deleted mutant in YCB–BSA–YE (0.01%) medium (Fig. 1A and D). The spot assay somehow masked the minor growth delay of strain overexpressing RHB1 shown in the liquid medium (Fig. 1A). It is possible that the spot assay is not sensitive enough to detect a minor delay in cell growth. Overall, these results indicate that Rhb1 is involved in the expression of Sap2, which is critical for cell growth in media with protein as the major nitrogen source.

The TOR signaling pathway is also involved in regulating SAP2 expression. Rapamycin is an inhibitor of Tor kinase and forms a complex with FKBP12, a 12-kDa protein (28). S. cerevisiae cells treated with rapamycin express a phenotype that mimics that of cells undergoing nitrogen starvation (14). Previous research showed that mutants lacking Rhb1 are hypersensitive to rapamycin, suggesting that Rhb1 plays a role in TOR signaling (72). Figure 2A illustrates the close relationship among Rhb1, rapamycin, and Tor1. The rhl1-deleted mutant was rapamycin sensitive whereas the TOR1/ROR1 mutant was rapamycin resistant compared with the wild type (Fig. 2A). The C. albicans TOR1–/–TOR1 strain carries a TOR1–1 allele with a point mutation (TOR1519841) in the FKBP12 rapamycin-binding (FRB) domain of the Tor1 kinase (20). The TOR1–/–TOR1 strain is resistant to rapamycin, because the FKBP12–rapamycin complex cannot bind to Tor1 kinase with this mutation (20). Two independent constructs of the rhl1 deletion on the TOR1519841 mutant background were not as strongly resistant to rapamycin as TOR1–/–TOR1 (Fig. 2A). In fact, rhl1 deletion in the TOR1–/–TOR1 background showed slightly enhanced resistance to rapamycin compared with the rhl1-deleted mutant. These results suggest that deletion of RHB1 compensates for the defect in rapamycin binding to the mutant FRB domain of the Tor1 kinase. Rapamycin and the rhl1 deletion combined have an additional effect on the Tor1 kinase, thus reinforcing rapamycin susceptibility.

The level of Sap2 is altered in the rhl1-deleted strain and the strain overexpressing RHB1 when protein is the major nitrogen source (Fig. 1B and C). Thus, it is possible that both Rhb1 and Tor1 kinase are involved in regulating SAP2 gene expression. Total RNA was isolated and analyzed by reverse transcription-PCR (RT-PCR). After 10 h of growth in YCB–BSA–YE (0.01%) medium, the expression level of the SAP2 transcript was slightly higher in the rhl1-deleted strain than in the wild-type and RHB1-reconstituted strains (Fig. 2B). However, the expression of SAP2 transcripts was nearly undetectable in the strain overexpressing RHB1 after 10 h (Fig. 2B). Expression of SAP2 reached similar levels in all strains tested after 24 h. To determine the role of Tor1 kinase in SAP2 expression, the experiments in this study used synthetic defined (SD) medium, which contains no protein but has ammonium, a favorable nitrogen source, and a complete supplement mixture (CSM) of amino acids. The cultures were also treated with and without rapamycin. As expected, rapamycin induced SAP2 expression at a level greater than that seen with vehicle-treated control cells (Fig. 2C). The extracellular proteolytic activity of Sap2 was also assessed (38) by spotting the cells onto YCB–BSA–YE (0.01%) agar plates containing rapamycin. A high concentration of cells (∼2.5 × 10⁵ cells/spot) was used for each tested strain to compensate for the possible reduction in cell growth caused by rapamycin. The zones of proteolysis surrounding the cell spots represent the relative levels of protease secretion (38). The wild-type strain produced a larger proteolytic zone than the TOR1–/–TOR1 strain (Fig. 2D). The sap2-deleted strain served as a negative control and did not show a clear proteolytic zone (Fig. 2D). These results indicate that Tor1 kinase is involved in SAP2 expression and somehow affects the secretion of Sap2.

To further correlate the TOR signaling pathway with SAP2 expression, transcription factors that may be downstream of the Tor1 kinase were also examined during rapamycin treatment. In C. albicans, Gln3 and Gat1 are the downstream effectors of TOR signaling in regulating nitrogen catabolism (7). In C. albicans, Gln3 and Gat1 activate the Stp1 transcription factor, which in turn controls SAP2 expression (22). A time course analysis of SAP2 expression was performed using RT-PCR. SAP2 was activated with rapamycin treatment in wild-type cells, whereas a relatively low level of SAP2 was expressed in the TOR1–/–TOR1 strain (Fig. 3A). After rapamycin treatment, cells lacking Gln3 or Gat1 showed a delay and a decrease in SAP2 expression compared with wild-type cells. Moreover, the gln3Δ/gat1Δ double mutant showed an even lower level of SAP2 expression than the gln3Δ and gat1Δ single mutant strains (Fig. 3A). With rapamycin treatment, deletion of STP1 also decreased SAP2 expression (Fig. 3A). The sap2-deleted strain served as a negative control. This suggests that SAP2 expression controlled by TOR signaling involves Gln3 or Gat1 or both and is further activated by Stp1. To further determine the function of Stp1 in TOR signaling, this study examined the susceptibility of the stp1-deleted mutants to rapamycin. As with the gln3- and gat1-deleted mutants, the stp1-deleted mutants were resistant to rapamycin (Fig. 3B) (40). The C. cerevisiae stp1-deleted mutant is rapamycin sensitive (66), suggesting that the Stp1 proteins in the two budding yeasts may function differently.

The transcriptional activity of Gat1 and Stp1 was assessed with a one-hybrid analysis (64) using cells grown in YCB–BSA–YE (0.01%) medium (Fig. 3C). LexA-Gcn4 and LexA constructs served as positive and negative controls, respectively (31). Compared to wild-type cells, Gat1 and Stp1 showed relatively higher transcriptional activity in cells on the rhl1-deleted background. However, the transcriptional activity of Gat1 (but not Stp1) was substantially lower than that seen with the wild type in the RHB1 overexpression background (Fig. 3C). These results suggest that Rhb1 and Tor1 are involved in the activity of Gln3 and Gat1 in transcriptional regulation.

Tor1 and amino acid regulation of Sap2 protein level. Because Tor1 is involved in SAP2 transcription and somehow affects Sap2 secretion (Fig. 2B and C), we hypothesized that Tor1 may affect Sap2 directly at the protein level. This possibility was tested using a strain in which SAP2 is regulated by the Pet promoter (Fig. 1B). In this strain, SAP2 expression is likely to be activated by doxycycline independently of TOR signaling. When doxycycline was added, cells showed almost equal levels of SAP2 transcription throughout all examined time points, in both the presence and absence of rapamycin (Fig. 4A). How-
ever, the levels of both extracellular and intracellular Sap2 in the presence of rapamycin were higher than those in control cells without rapamycin treatment (Fig. 4B). A strain carrying a $P_{\text{tet}}$-GFP fusion was also tested to rule out the possibility that the rapamycin-related effect on the level of Sap2 protein was due to the construction of the $P_{\text{tet}}$ promoter. GFP was expressed at similar levels under the same growth conditions (see Fig. S4 in the supplemental material). The data suggest that

**FIG 2** Tor1 kinase regulates SAP2 expression and affects Sap2 protease secretion. (A) Epistatic interaction between Rhb1 and Tor1 kinase. Tenfold serial dilutions of each strain were prepared and spotted onto YPD with 0.01-µg/ml rapamycin or with 0.1% methanol (MeOH [the vehicle control]). Plates were incubated at 30°C for 2 days. Data are representative of at least 3 independent experiments with identical results. Cell numbers are shown at the top of the panels. (B) SAP2 expression in different *C. albicans* strains. Cells were grown as described in the Fig. 1A legend for 10 and 24 h, and SAP2 expression was analyzed with RT-PCR. *EFB1* served as an endogenous control. Cn, number of cycles in the PCRs. The semiquantitative levels of *SAP2* induction were calculated and plotted. (C) Induction of *SAP2* expression by rapamycin treatment. The SC5314 strain was incubated in SD medium at 30°C until reaching mid-log phase. The cell pellets were washed and subsequently subcultured in SD (−), SD containing 0.2% methanol (MeOH [the vehicle control]), or SD containing 0.2-µg/ml rapamycin. After cells were grown for the indicated times, the level of SAP2 expression was detected with RT-PCR. *EFB1* served as an endogenous control. The semiquantitative levels of *SAP2* induction were calculated and plotted. m, minutes. (D) Assay for Sap2 secretion by BSA degradation. Approximately 2.5 × 10⁵ cells of the SC5314, JRB12 (*TOR1-1/TOR1*), and SAP2MS4A (*sap2Δ/sap2Δ*) strains were spotted on YCB–BSA–YE (0.01%) agar plates containing rapamycin (0.01 µg/ml) and incubated at 37°C for 4 days. The double arrows indicate the diameter of the proteolytic zone.
Gln3, Gat1, and Stp1 regulate SAP2 expression downstream of the Tor1 kinase. (A) The gln3Δ, gat1Δ, and stp1Δ-deleted strains attenuate rapamycin-induced SAP2 expression. Cells were grown in YPD medium at 30°C until reaching the mid-log phase. The cell pellets were washed and subcultured in YPD with and without 0.2 μg/ml of rapamycin. After cells were grown for the indicated times, the level of SAP2 expression was detected with RT-PCR. The strains used in this experiment include SC5314 (wild type), JRB12 (TOR1Δ/TOR1), CCT-D1 (rhb1Δ/rhb1Δ), STP1M4A (stp1Δ/stp1Δ), GLN3M4A (gln3Δ/gln3Δ), GAT1M4A (gat1Δ/gat1Δ), Δgln3GAT1M4A (gln3Δ/gln3Δ gat1Δ/gat1Δ), and SAP2MS4A (sap2Δ/sap2Δ). EFB1 served as an endogenous control. The semiquantitative levels of SAP2 induction were calculated and plotted. The sample of wild type (without rapamycin treatment) from time zero was used as the calibrator. m, minutes. (B) Stp1 is involved in the TOR signaling pathway. SC5314, JRB12 (TOR1Δ/TOR1), STP1M4A, and CHIA-D1 (the last 2 are independent stp1Δ/stp1Δ mutants as shown in the third and fourth lanes from the top, respectively) were incubated in YPD overnight. The cell pellets were washed, serially diluted, spotted onto YPD agar plates with 0.01 μg/ml rapamycin or 0.1% methanol (MeOH [the vehicle control]), and incubated at 30°C for 2 days. Data are representative of 3 independent experiments with identical results. Cell numbers are shown at the top of the panels. (C) Yeast one-hybrid analysis demonstrated that Rhb1 affects the transcriptional activity of Gat1 and Stp1. Strains with and without the LexA operator upstream of the basal promoter of the lacZ reporter gene are labeled LexA operator (CCR1 background) and basal (COP1 background), respectively. COP1 and CCR1 were constructed in the rhb1Δ-deleted (rhb1Δ/rhb1Δ) or RHBI-overexpressing (P<sub>ADH1</sub>-RHB1) background. Cells were incubated in YCB–BSA–YE (0.01%) medium at 30°C for 5.5 h, and the LacZ activity modulated by Stp1-LexA or LexA-Gat1 binding to the LexA operator was measured with a liquid β-galactosidase assay. β-Galactosidase data are shown in Miller units and represent averages of the results of 3 independent experiments. *, P ≤ 0.05; **, P ≤ 0.01; ***, P ≤ 0.005. The error bars show standard deviations.

FIG 3 Gln3, Gat1, and Stp1 regulate SAP2 expression downstream of the Tor1 kinase. (A) The gln3Δ, gat1Δ, and stp1Δ-deleted strains attenuate rapamycin-induced SAP2 expression. Cells were grown in YPD medium at 30°C until reaching the mid-log phase. The cell pellets were washed and subcultured in YPD with and without 0.2 μg/ml of rapamycin. After cells were grown for the indicated times, the level of SAP2 expression was detected with RT-PCR. The strains used in this experiment include SC5314 (wild type), JRB12 (TOR1Δ/TOR1), CCT-D1 (rhb1Δ/rhb1Δ), STP1M4A (stp1Δ/stp1Δ), GLN3M4A (gln3Δ/gln3Δ), GAT1M4A (gat1Δ/gat1Δ), Δgln3GAT1M4A (gln3Δ/gln3Δ gat1Δ/gat1Δ), and SAP2MS4A (sap2Δ/sap2Δ). EFB1 served as an endogenous control. The semiquantitative levels of SAP2 induction were calculated and plotted. The sample of wild type (without rapamycin treatment) from time zero was used as the calibrator. m, minutes. (B) Stp1 is involved in the TOR signaling pathway. SC5314, JRB12 (TOR1Δ/TOR1), STP1M4A, and CHIA-D1 (the last 2 are independent stp1Δ/stp1Δ mutants as shown in the third and fourth lanes from the top, respectively) were incubated in YPD overnight. The cell pellets were washed, serially diluted, spotted onto YPD agar plates with 0.01 μg/ml rapamycin or 0.1% methanol (MeOH [the vehicle control]), and incubated at 30°C for 2 days. Data are representative of 3 independent experiments with identical results. Cell numbers are shown at the top of the panels. Cells were incubated in YCB–BSA–YE (0.01%) medium at 30°C for 5.5 h, and the LacZ activity modulated by Stp1-LexA or LexA-Gat1 binding to the LexA operator was measured with a liquid β-galactosidase assay. β-Galactosidase data are shown in Miller units and represent averages of the results of 3 independent experiments. *, P ≤ 0.05; **, P ≤ 0.01; *** P ≤ 0.005. The error bars show standard deviations.
DISCUSSION

The Ras superfamily of small GTPases is generally classified into 5 families, including Ras, Rho, Rab, Arf, and Ran (3). Of the Ras members, Ras homolog enriched in brain (Rheb) is a novel and unique small G protein (3). Most of the information on Rheb has been gathered from mammal studies. Translationally controlled tumor protein (TCTP; also known as p23) and tuberous sclerosis protein (TSC; also known as hamartin and tuberin) are among the downregulated genes in the rheb1-deleted mutant. GAP1 encodes a general amino acid permease, and EFG1 encodes a transcription factor controlling C. albicans morphogenesis (52, 53). HIP1 encodes an uncharacterized protein regulated by Gcn2 and Gcn4 (70), and its sequence shows the best hit with S. cerevisiae GAP1. Real-time quantitative PCR verified the expression patterns of GAP1, GAPA, and HIP1 (Fig. 6B).

Identification of Rhb1-regulated genes in C. albicans. This study also investigated possible target genes of C. albicans Rhb1 with DNA microarray analysis. Both wild-type and rhb1-deleted strains were grown in SD medium to mid-log phase, and total RNA was isolated. Samples were prepared and labeled with Cy3 or Cy5 fluorescent dye before data analysis. Using a $P$ value of $<0.0148$ as the cutoff, expression of 109, 17, and 6 gene transcripts changed at least 1.5-, 2-, and 3-fold, respectively, in the rhb1-deleted mutant compared with levels in the wild type (Fig. 6A). The following discussion reviews the highlights of the 113 genes, and the details are listed in Tables S1 and S2 in the supplemental material. In addition to SAP2, the expression of genes such as MEP2, GAP2, RBT1, OPT1, and ALS3 was upregulated in the rhb1 mutant. MEP2 encodes an ammonium sensor and transporter (10), and its regulation by Rhb1 is consistent with previous findings (72). The GAP2 and OPT1 gene products are a general amino acid permease and an oligopeptide transporter, respectively (47). The RBT1 gene product is predicted to be a cell wall protein (6). ALS3 encodes an adhesin that plays a complementary role in C. albicans biofilm formation (52, 53). Tor1 kinase also regulates RBT1 and ALS3 (6), and GAP1, HIP1, and EFG1 are among the downregulated genes in the rhb1-deleted mutant. GAP1 encodes a general amino acid permease, and EFG1 encodes a transcription factor controlling C. albicans morphogenesis (52, 53). HIP1 encodes an uncharacterized protein regulated by Gcn2 and Gcn4 (70), and its sequence shows the best hit with S. cerevisiae GAP1. Real-time quantitative PCR verified the expression patterns of GAP1, GAP2, and HIP1 (Fig. 6B).

FIG 4 Tor1 kinase is involved in Sap2 level regulation. (A) The SAP2ex4A strain carrying doxycycline-inducible SAP2 was first grown to an OD$_{600}$ of 2.5 to 3 in YCB–BSA–YE (0.01%) medium containing 30 lg/ml doxycycline at 30°C for 6 h. The cultures were then equally divided into tubes containing 0.2 lg/ml rapamycin or 2% methanol (MeOH [the vehicle control]). The cells were incubated and collected at the indicated times. The expression of SAP2 was examined with RT-PCR. EFB1 served as an endogenous control and was used for the semiquantitation of SAP2 expression. m, minutes. (B) Protein level of Sap2 induced by rapamycin. The levels of intracellular and extracellular Sap2 were detected in the SAP2ex4A strain grown as described for panel A. Whole-cell extract (20 lg) or 20 lg of supernatant from each sample was analyzed with SDS-PAGE and immunoblotted using monoclonal anti-Sap2. The nonspecific band served as the loading control. The semiquantitative levels of Sap2 protein were calculated and plotted. m, minutes.

TOR signaling is involved in regulating SAP2 transcription and further affects the expression of Sap2 protein.

This discussion and previous research (22) indicate that nitrogen depletion and the presence of protein function as signals for SAP2 activation in C. albicans through Rhb1-TOR signaling. This study further determined whether the Sap2 protein level is also affected by the availability of amino acids, another possible source of nitrogen. We detected Sap2 in response to treatment with amino acids and rapamycin (Fig. 5). After 3.5 h of incubation with doxycycline, the intracellular levels of Sap2 were significantly abated in the strain in which SAP2 was regulated by the Ptet promoter when a combination of amino acids (CSM) was added to the nitrogen-poor YCB–BSA–YE (0.01%) medium (Fig. 5A). The reduction of Sap2 protein levels by a high concentration of amino acids did not occur in the presence of rapamycin (Fig. 5A). In the amino acid-containing SD medium, Sap2 was not detected even when SAP2 transcription was turned on with doxycycline (Fig. 5B). In contrast, Sap2 was first detected after cells were treated with rapamycin for 1 h (Fig. 5B). These results indicate that amino acid starvation is also a signal for Sap2 protein expression through TOR signaling.
rampicin (data not shown). The mechanisms of VPS-mediated Sap2 secretion and Rhb1-TOR signaling are under investigation in our laboratory.

The transcription factors Gln3 and Gat1 regulate another transcriptional factor, Stp1, which in turn controls Sap2 (22). This report links the Rhb1-TOR signaling pathway with this Stp1-mediated Sap2 regulation (Fig. 3A and B). The Csy1, Ptr3, and Ssy5 (SPS) sensor complex likely regulates the activities of C. albicans Stp1 and another related transcriptional factor, Stp2 (47). In the presence of amino acids, Stp1 and Stp2 undergo proteolytic cleavage by the activated SPS complex. Under these conditions, processed Stp1 and Stp2 lack N-terminal inhibitory domains and are translocated from the cytosol to the nucleus. Processed Stp1 regulates protein utilization genes such as Sap2 and OPT1, whereas processed Stp2 regulates genes related to amino acid utilization, including the amino acid permeases Gap1 and Gap2 (47). Expression of some other genes (e.g., an oligopeptide transporter [OPT3]) can be induced by either processed Stp1 or Stp2. DNA microarray analysis revealed that OPT1, GAP2, and SAP2 were upregulated after deletion of RHB1, whereas GAP1 and HIP1 were downregulated (see Tables S1 and S2 in the supplemental material). These permeases may be responsible for assimilating extra-

regulate Rheb (25, 57). Rheb is likely a positive regulator of the mTOR kinase and activates mTORC1 signaling (42).

The functions of Rhb1 (the homolog of Rheb) in fungi are not well characterized. In S. cerevisiae, Rhb1 functions in the uptake of arginine (75). However, no homolog of mammalian Tsc2 has been found in the genome of S. cerevisiae (3). Whether environmental signals can be conveyed from Rhb1 to TORC1 remains unknown. Rhb1 regulates amino acid uptake, mating, cell growth, cell cycle progression, and stress response in S. pombe (44, 73, 74, 76). Mutations in TSC2 cause defects in the uptake of arginine and leucine (77, 80) and lead to a delayed response in nitrogen starvation-mediated G1 arrest (48, 78). In fission yeast, TORC1 controls cell proliferation in response to nutrient signals and acts downstream of Rhb1 (51, 76).

Previous research identified Tsc2 and Rhb1 in C. albicans and linked Rhb1 to the Tor1 kinase (72). Rhb1 and Tor1 are involved in nitrogen starvation-induced morphogenesis by controlling MEP2 and cell wall integrity (6, 72). The results of the current study also indicate that the Rhb1-TOR signaling pathway controls the expression of the C. albicans virulence factor Sap2. In medium containing protein as the major nitrogen source, RHBI overexpression attenuates the expression of Sap2 before 24 h but is otherwise normal (Fig. 1C). In the absence of RHBI, cells express Sap2 before other strains but otherwise function as normal (Fig. 1C). Although intrinsic growth defects appeared in the rhb1-deleted strain (Fig. 1D), a higher level of Sap2 may somehow compensate for this growth defect and result in a similar growth rate in the YCB–BSA–YE (0.01%) medium (Fig. 1A).

Rapamycin treatment also activated Sap2 in nitrogen-rich and no-protein conditions, which are generally unfavorable for Sap2 transcription (Fig. 2B). Rapamycin also enhanced the expression of Sap2 (Fig. 2F). The increased expression of Sap2 and its gene product somehow produced highly efficient Sap2 secretion (Fig. 1C and 2C). This result agrees with previous research showing that Sap synthesis and secretion are tightly coupled (30). Although the mechanisms of this process remain unclear, almost all S. cerevisiae mutants lacking vacuolar protein sorting (VPS) genes show susceptibility to rapamycin (82). Researchers recently reported that C. albicans mutants lacking VPS1 and VPS4 were defective in Sap2 secretion in an extracellular environment (8, 38). Moreover, we also tested a vps4-deleted strain and a strain in which VPS1 was repressed by doxycycline and found that both were hypersensitive to rapamycin (data not shown). The mechanisms of VPS-mediated Sap2 secretion and Rhb1-TOR signaling are under investigation in our laboratory.

The transcription factors Gln3 and Gat1 regulate another transcriptional factor, Stp1, which in turn controls Sap2 (22). This report links the Rhb1-TOR signaling pathway with this Stp1-mediated Sap2 regulation (Fig. 3A and B). The Csy1, Ptr3, and Ssy5 (SPS) sensor complex likely regulates the activities of C. albicans Stp1 and another related transcriptional factor, Stp2 (47). In the presence of amino acids, Stp1 and Stp2 undergo proteolytic cleavage by the activated SPS complex. Under these conditions, processed Stp1 and Stp2 lack N-terminal inhibitory domains and are translocated from the cytosol to the nucleus. Processed Stp1 regulates protein utilization genes such as Sap2 and OPT1, whereas processed Stp2 regulates genes related to amino acid utilization, including the amino acid permeases Gap1 and Gap2 (47). Expression of some other genes (e.g., an oligopeptide transporter [OPT3]) can be induced by either processed Stp1 or Stp2. DNA microarray analysis revealed that OPT1, GAP2, and SAP2 were upregulated after deletion of RHB1, whereas GAP1 and HIP1 were downregulated (see Tables S1 and S2 in the supplemental material). These permeases may be responsible for assimilating extra-

FIG 5 Amino acid availability plays a role in the protein level regulation of Sap2. A. Reduction of Sap2 protein levels induced by a high concentration of amino acid did not occur in the presence of rapamycin. The SAP2ex4A strain carrying doxycycline-inducible SAP2 was first grown to mid-log phase in YC–BSA–YE (0.01%) medium containing 30 μg/ml doxycycline at 30°C (Fig. 4). The cultures were then equally divided into tubes containing 1.8× CSM plus 0.2 μg/ml rapamycin (rapa) or 1.8× CSM plus 0.2% methanol (MeOH [the vehicle control]). The cells were incubated and collected at the indicated times. Intracellular protein samples (20 μg) were analyzed with SDS-PAGE and immunoblotted using monoclonal anti-Sap2. Time zero indicates a sample without rapamycin or methanol. The semiquantitative levels of Sap2 protein induced by rapamycin were calculated and plotted. m, minutes. (B) Sap2 protein level in SD medium with and without rapamycin. The SAP2ex4A strain was incubated in SD containing 30 μg/ml doxycycline at 30°C until reaching mid-log phase. The cell pellets were washed and resuspended in fresh SD medium with 30 μg/ml doxycycline. The cultures were grown and collected at the indicated times. Each sample (20 μg) was analyzed with SDS-PAGE and immunoblotted using monoclonal anti-Sap2. Time zero indicates a sample without rapamycin or methanol.
FIG 6 Identification of Rhb1 target genes by the use of DNA microarray analysis. (A) Summary of the fold change thresholds of the differentially expressed genes in the rhb1Δ-deleted mutant (CCT-D1) compared with the wild type (SC5314). RNAs were collected after both strains were grown to mid-log phase in SD medium at 30°C. (B) Relative expression levels of three general amino acid permease genes: GAP1, HIP1, and GAP2. Quantitative real-time PCR was performed for GAP1, HIP1, and GAP2 in the wild-type (SC5314), CCT-D1 (rhb1Δ/rhb1Δ), and CCT-RD1 (RHB1-reconstituted) strains. Cells were grown in SD medium for 4 h to mid-log phase under the same conditions used in the microarray experiment. The threshold cycle (C_T) value of each gene was derived from the average of the results of 3 experiments. The ΔC_T value was determined by subtracting the average ΔC_T of endogenous control EFB1 from the average C_T of the gene tested. The ΔΔC_T of each gene was calculated by subtracting the ΔC_T value of the corresponding calibration value (wild-type sample). The average ΔΔC_T and standard deviation values were determined from experiments performed in triplicate. The relative expression level of each gene is 2^-ΔΔC_T, ***, P ≤ 0.005. The error bars show the standard deviation.
Sap2 protein level by TOR signaling is part of the cellular response to amino acid availability. Starvation resulting from amino acid deficiency activates the GAAC pathway in *S. cerevisiae* (29), and the GAAC is integrated with the TOR signaling pathway (68). The GAAC pathway is poorly understood in *C. albicans*. Although Gcn4 regulates the expression of amino acid synthetic genes in response to amino acid starvation, regulation of Gcn4 mRNA does not seem to occur (71). The *C. albicans* ortholog of Gcn2 also has limited involvement in the cellular response to amino acid starvation. This is likely because Gcn2 inactivation only partially attenuates cell growth under conditions of amino acid starvation (70). However, the regulation of amino acid biosynthetic genes is still dependent on Gcn4 (70). The DNA microarray analysis in this study confirms that several amino acid biosynthetic and Gcn4 target genes were differentially expressed in the *rhp1* mutant (see Tables S1 and S2 in the supplemental material). This suggests that GAAC regulation in *C. albicans* may occur through the Rhp1-TOR signaling pathway. Future research on this topic will investigate the details of *C. albicans* GCN-like regulation mediated by Rhp1 and TOR signaling.

**ACKNOWLEDGMENTS**

We are grateful to Alistair J. Brown (University of Aberdeen, United Kingdom), Maris Cardenas (Duke University), Samuel Lee (University of New Mexico Health Science Center), and Joachim Morschhäuser (Universität Würzburg, Germany) for providing plasmids and strains. We also thank Yi-Ta Chen (National Tsing Hua University, Taiwan), Shu-Jen Chou, and Shu-Hsing Wu (DNA Microarray Core Laboratory, Institute of Plant and Microbial Biology, Academia Sinica, Taiwan) for the technical assistance in the fabrication of DNA microarray of *C. albicans*. This work was supported by grants NSC98-2311-B-007-010-MY3 and NSC99-2627-B-007-007 (to C.-Y.L.) and NSC97-2118-M-007-004-MY2 (to W.-P.H.) from the National Science Council (Taiwan).

**FIG 7** Model depicting Rhb1-TOR signaling in the regulation of SAP2 expression. In the absence of Rhb1 ("1") or in cells treated with rapamycin ("2"), TOR signaling directly or indirectly affects SAP2 expression by transmitting the signal from Gln3 and Gat1 to activate STP1 expression. The SPS complex processes Stp1, and the active form of Stp1 in turn triggers SAP2 expression. Sap2 is processed before secretion into the environment. Enriched extracellular amino acids from extracellular proteins digested by Sap2 or other proteases may also transmit a signal to activate the Tor1 kinase ("3") (which may or may not occur through the SPS sensor) to inhibit SAP2 expression (and thus the Sap2 protein level) and other SPS-responsive genes. CM, cell membrane; NM, nuclear membrane. An asterisk indicates the active form of a particular protein, and a dashed line represents a hypothetical correlation.
