Spectrum of Hidden-Charm, Open-Strange Exotics in the Dynamical Diquark Model

Jesse F. Giron, Richard F. Lebed, and Steven R. Martinez

Department of Physics, Arizona State University, Tempe, AZ 85287, USA

(Dated: June, 2021)

The observation by BESIII and LHCb of states with hidden charm and open strangeness \((c\bar{c}qs)\) presents new opportunities for the development of a global model of heavy-quark exotics. Here we extend the dynamical diquark model to encompass such states, using the same values of Hamiltonian parameters previously obtained from the nonstrange and hidden-strange sectors. The large mass splitting between \(Z_{cs}(4000)\) and \(Z_{cs}(4220)\) suggests substantial SU(3)\(^{\text{flavor}}\) mixing between all \(J^P = 1^+\) states, while their average mass compared to that of other sectors offers a direct probe of flavor octet-singlet mixing among exotics. We also explore the inclusion of \(\eta\)-like exchanges within the states, and find their effects to be quite limited. In addition, using the same diquark-mass parameters, we find \(P_c(4312)\) and \(P_{cs}(4459)\) to fit well as corresponding nonstrange and open-strange pentaquarks.

Keywords: Exotic hadrons, diquarks

I. INTRODUCTION

The spectrum of known heavy-quark exotic hadrons continues to expand frequently, with about 50 candidates observed to date. Almost all have a valence light-flavor content consisting of only \(q \equiv u + d\) quarks, but very recently some states with open strangeness have been detected in both the open-charm \([1, 2]\) \((\bar{c}\bar{d}su)\) and hidden-charm sectors. In the latter, both a pentaquark \([3]\) \((\bar{c}\bar{c}uds)\) state and tetraquark \([4, 5]\) \((\bar{c}\bar{c}u\bar{s})\) states have been observed.

Multiple reviews summarizing both experimental and theoretical advances in this field have appeared in recent years \([6–16]\). Several competing theoretical frameworks (di-hadron molecular states, bound states of diquarks, threshold enhancements, etc.) have been developed for years, but no single scheme has yet emerged as a dominant paradigm to explain all the new states, analogous to the way that quark-potential models successfully elucidate the conventional \(cc\) and \(bb\) sectors \([17]\).

Since a number of the observed exotics decay to final states like \(J/\psi \phi\) or \(D^{(*)}_s \\bar{D}^{(*)}_s\), they possess a presumptive \(c\bar{c}ss\) valence content. The advent of \(c\bar{c}qg\) states thus introduces an intermediate case between \(c\bar{c}qg^2\) and \(c\bar{c}ss\) cases, and therefore not only provides an opportunity to examine whether a particular theoretical picture can successfully incorporate data from all of these flavor sectors, but also examines the manifestation of light-quark SU(3)\(^{\text{flavor}}\) for the first time outside of conventional mesons and baryons.

The new data in the hidden-charm, open-strange sector itself is quite interesting. BESIII observes a structure \([4]\) in the \(K^+\) recoil spectrum of \(e^+e^- \rightarrow K^+(\bar{D}_s^+D^{(*)^0_0} + D_s^+\bar{D}^{(*)}_s^0)\) near the 2-charmed-meson thresholds (about 3975 and 3977 MeV, respectively). For this \(Z_{cs}(3985)\) state, they obtain:

\[
\begin{align*}
  m_{Z_{cs}} &= 3982.5^{+1.8}_{-2.6} \pm 2.1 \text{ MeV}, \\
  \Gamma_{Z_{cs}} &= 12.8^{+5.3}_{-4.4} \pm 3.0/\text{MeV}, \\
  J^P &= 1^+. 
\end{align*}
\]

and \(J^P = 1^+.\) Meanwhile, LHCb reports 2 states \([5]\) decaying to \(J/\psi K^+\),

\[
\begin{align*}
  m_{Z_{cs}^+}(4000) &= 4003 \pm 6^{+4}_{-5} \text{ MeV}, \\
  \Gamma_{Z_{cs}^+}(4000) &= 131 \pm 15 \pm 26 \text{ MeV}, \\
  m_{Z_{cs}^+}(4220) &= 4216 \pm 24^{+43}_{-27} \text{ MeV}, \\
  \Gamma_{Z_{cs}^+}(4220) &= 233 \pm 52^{+97}_{-73} \text{ MeV},
\end{align*}
\]

with \(Z_{cs}(4000)\) carrying \(J^P = 1^+\) and \(Z_{cs}(4220)\) favored to carry \(J^P = 1^+\). The masses of \(Z_{cs}(3985)\) and \(Z_{cs}(4000)\) are compatible with them being the same state, but their measured widths are wildly different. For the purposes of this paper, we assume that only a single light \(Z_{cs}\) state exists near 4.0 GeV, the discrepancy in width measurements perhaps arising from effects caused by interactions with the nearby charmed-meson thresholds \([18]\) LHCb also observes a baryonic structure \([3]\) \(P_{cs}(4459)\) decaying to \(J/\psi A\):

\[
\begin{align*}
  m_{P_{cs}(4459)} &= 4458.8 \pm 2.9^{+4.7}_{-1.1} \text{ MeV}, \\
  \Gamma_{P_{cs}(4459)} &= 17.3 \pm 6.5^{+8.0}_{-5.7} \text{ MeV},
\end{align*}
\]

although its \(J^P\) value is not yet determined.

Quite an extensive body of theoretical work on the hidden-charm, open-strange hadrons exists. For example, in the meson sector whose study forms the bulk of

2 This opinion is not universal. For example, Ref. \([18]\) treats \(Z_{cs}(3985)\) and \(Z_{cs}(4000)\) as separate states belonging to distinct SU(3)\(^{\text{flavor}}\) multiplets.
this work, several papers [19–24] predate the experimental observations, while multiple studies followed the announcement of the BESIII result but preceded the appearance of the LHCb paper [25–47], and yet others appeared subsequent to the LHCb results [18, 48–55]. As one might imagine, this body of work encompasses multiple approaches, including molecular and diquark models, chiral-quark models, and QCD sum rules, among others.

The present work uses the dynamical diquark model, initially introduced in Ref. [56] as a theoretical picture to explain how relatively compact color-triplet diquark quasiparticle pairs can form spatially extended tetraquark states, and extended in Ref. [57] to describe pentaquarks as color-triplet diquark-triquark quasiparticle bound states. The picture is developed in Ref. [58] into a predictive model by noting that the static interaction potential between the heavy color-triplet quasiparticles is the same one as appearing in lattice simulations of heavy quarkonium and its hybrids. The multiplet band structure for $c\bar{c}q\bar{q}$ and $c\bar{c}q\bar{q}q$ states is studied numerically in Ref. [59]; the fine structure of the ground-state (S-wave) $c\bar{c}q\bar{q}$ multiplet is examined numerically in Ref. [60] and that of the P-wave multiplet appears in Ref. [61]. An analogous study of the $b\bar{b}q\bar{q}$ and $c\bar{c}s\bar{s}$ systems is presented in Ref. [62], and the $c\bar{c}s\bar{s}$ states are investigated in Ref. [63]. Radiative transitions between exotic states are computed in Ref. [64].

Our analysis of $ccq\bar{s}$ exotics here directly interpolates between the analysis of $ccq\bar{q}$ in Ref. [60] and $c\bar{c}s\bar{s}$ in Ref. [62], and uses the same numerical inputs. However, we find that a careful treatment of the SU(3)$_{\text{flavor}}$ structure introduces one new parameter, related to octet-singlet mixing. In addition, we allow for the possibility of an $\eta$-like exchange between the diquarks analogous to the $\pi$-like exchange already present in the original model [60], but show that its effects are quite limited by constraints from the phenomenology of the $ccq\bar{q}$ sector. We find that the known phenomenology of the open-strange sector does indeed follow from that of the other sectors, despite superficially appearing quite different. We also carry out an analogous exercise for nonstrange and open-strange hidden-charm pentaquark states [$P_{cc}(4459)$ currently being the only known example of the latter], and obtain remarkably satisfactory results.

This paper is organized as follows. In Sec. II we define the multiplets of states in terms of eigenstates of both good diquark spin and good heavy-quark/light-quark spins. Section III presents the Hamiltonian for the $ccq\bar{q}$ and $c\bar{c}s\bar{s}$ sectors, now including a possible term from $\eta$-like exchanges, and computes all relevant matrix elements. Section IV performs the same analysis for the $c\bar{c}s\bar{s}$ sector, and discusses possible mixing between multiplets whose nonstrange members carry opposite C parity. In Sec. V we discuss the effects of octet-singlet mixing on the analysis and present numerical results, and in Sec. VI we summarize and conclude.

### II. STATES OF THE MODEL

A cataloguing of the $Q\bar{Q}q\bar{q}$ or $Q\bar{Q}qq\bar{q}$ states in the dynamical diquark model, where $q, q', q_i \in \{u, d\}$, first appears in Ref. [58]. The same notation, with small modifications, is applied to $c\bar{c}s\bar{s}$ in Ref. [62] and to $c\bar{c}c\bar{c}$ in Ref. [63]. All confirmed exotic candidates to date have successfully been accommodated within the lowest ($\Sigma_q^+$) Born-Oppenheimer potential of the gluon field connecting the heavy diquark $[\bar{Q}q]$-antidiquark $[\bar{Q}'q']$ or diquark-triquark $[\bar{Q}(q_1q_2)]$ quasiparticles. In all cases, $\delta, \bar{\delta}, \bar{\theta}$ are assumed to transform as color triplets (or antitriplets) and each quasiparticle contains no internal orbital angular momentum.

In the case of $Q\bar{Q}q\bar{q}$, the classification scheme then begins with 6 possible core states in which the quasiparticle pair lie in a relative $S$ wave. Indicating the total spin $s$ of a diquark $\delta$ by $s_\delta, s_\bar{\delta}$ and using a subscript on the full state to indicate its total spin, one obtains the spectrum

$$J^{PC} = 0^{++} : X_0 \equiv |0_\delta, 0_\bar{\delta}\rangle_0 , \quad X_0' \equiv |1_\delta, 1_\bar{\delta}\rangle_0 ,$$
$$J^{PC} = 1^{++} : X_1 \equiv \frac{1}{\sqrt{2}} \left[ |0_\delta, 0_\bar{\delta}\rangle_1 + |0_\delta, 1_\bar{\delta}\rangle_1 \right] ,$$
$$J^{PC} = 1^{-+} : Z \equiv \frac{1}{\sqrt{2}} \left[ |0_\delta, 0_\bar{\delta}\rangle_1 - |0_\delta, 1_\bar{\delta}\rangle_1 \right] ,$$
$$J^{PC} = 2^{++} : X_2 \equiv |1_\delta, 1_\bar{\delta}\rangle_2 .$$

Since 4 quark angular momenta are being combined, one may transform these states into other convenient bases by means of 9$y$ angular momentum recoupling coefficients. In particular, in the basis of good total heavy-quark ($Q\bar{Q}$) and light-quark ($q\bar{q}'$) spin, the transformation reads

$$\langle (s_q s_\bar{q})s_q s_\bar{q}', (s_Q s_\bar{Q})s_Q s_\bar{Q}, S \mid (s_q s_\bar{q})s_\delta, (s_Q s_\bar{Q})s_\bar{\delta}, S \rangle = \left[ |s_q s_\bar{q}||s_Q s_\bar{Q}||s_\delta s_\bar{\delta}, S \rangle \right]^{1/2} \left\{ \begin{array}{c} s_q s_\bar{q} \\ s_Q s_\bar{Q} \\ s_\delta s_\bar{\delta} \end{array} \right\} ,$$

with $[s] \equiv 2s + 1$ signifying the multiplicity of a spin-$s$ state. Using Eqs. (4) and (5), one then obtains

$$J^{PC} = 0^{++} : X_0 = \frac{1}{2} |0_{q\bar{q}'}, 0_{Q\bar{Q}}\rangle_0 + \frac{\sqrt{3}}{2} |1_{q\bar{q}'}, 1_{Q\bar{Q}}\rangle_0 ,$$
$$X_0' = \frac{\sqrt{3}}{2} |0_{q\bar{q}'}, 0_{Q\bar{Q}}\rangle_0 - \frac{1}{2} |1_{q\bar{q}'}, 1_{Q\bar{Q}}\rangle_0 ,$$
$$J^{PC} = 1^{++} : X_1 = |1_{q\bar{q}'}, 1_{Q\bar{Q}}\rangle_1 ,$$
$$J^{PC} = 1^{-+} : Z = \frac{1}{\sqrt{2}} \left( |1_{q\bar{q}'}, 0_{Q\bar{Q}}\rangle_1 - |0_{q\bar{q}'}, 1_{Q\bar{Q}}\rangle_1 \right) ,$$
$$Z' = \frac{1}{\sqrt{2}} \left( |1_{q\bar{q}'}, 0_{Q\bar{Q}}\rangle_1 + |0_{q\bar{q}'}, 1_{Q\bar{Q}}\rangle_1 \right) ,$$
$$J^{PC} = 2^{++} : X_2 = |1_{q\bar{q}'}, 1_{Q\bar{Q}}\rangle_2 .$$

In this work the octet-singlet mixing is of a basis of states carrying a unique value of $s_{Q\bar{Q}}$ and of $s_{q\bar{q}'}$. 
These states are $X_1$ and $X_2$ [as seen in Eqs. (6)], and

\[
\begin{align*}
X_0 &\equiv |0_{qq'},0_{\bar{q}Q}\rangle_0 = \frac{1}{2} X_0 + \frac{\sqrt{3}}{2} X'_0,
X'_0 &\equiv |1_{qq'},1_{\bar{q}Q}\rangle_0 = \frac{1}{2} X_0 - \frac{1}{2} X'_0,
\tilde{Z} &\equiv |1_{qq'},0_{\bar{q}Q}\rangle_1 = \frac{1}{\sqrt{2}} (Z' + Z),
\tilde{Z}' &\equiv |0_{qq'},1_{\bar{q}Q}\rangle_1 = \frac{1}{\sqrt{2}} (Z' - Z). \quad (7)
\end{align*}
\]

Including $(u, d)$ light-quark flavor produces 12 states: 6 each with $I=0$ and $I=1$, and spin structures in the form of Eqs. (4), (6), or (7). The basis of Eqs. (7) in particular is ideal for discussing SU(3)$_{\text{flavor}}$ multiplets: A state component like $1_{u\bar{u}}$ is a pure flavor octet that transforms under spin and flavor analogously to $K^{*+}$ (although in a diquark model it comprises a mixture of color-singlet and color-octet components). The full SU(3)$_{\text{flavor}}$ structure of the multiplet $\Sigma_3^+(1S)$ thus consists of 6 octets and 6 singlets. A study of the possible mixing of states with the same $J^P$ between different SU(3)$_{\text{flavor}}$ octets, or of octet-singlet mixing, form two principal theory innovations of this work.

The $Q\bar{Q}qq'$ states in the multiplet $\Sigma_3^+(1S)$ are sufficient to accommodate all particles considered in this work. However, we note that Ref. 58 also provides a classification of orbitally excited states (the multiplets $\Sigma_4^+(nP)$ appearing in Ref. 60), as well as states in excited-gluon Born-Oppenheimer potentials such as $\Pi_4^+$ (which are exotic analogues to hybrid mesons), and pentaquark states $Q\bar{Q}qq_1q_2$.

### III. REVIEW OF $c\bar{c}qq'$ AND $c\bar{c}ss\bar{s}$ SECTOR

#### A. $c\bar{c}qq'$ Sector

For hidden heavy-flavor exotics containing only $u$ and/or $d$ light valence quarks, we write the following Hamiltonian:

\[
H = M_0 + \Delta H_{\kappa_Q} + \Delta V_0 + \Delta V_\bar{v}
= M_0 + 2\kappa_Q (s_q \cdot s_{Q} + s_{\bar{q}} \cdot s_{\bar{Q}}) + V_0 (\tau_q \cdot \tau_{\bar{q}}) (\sigma_q \cdot \sigma_{\bar{q}})
+ V_\bar{v} (\lambda^{\alpha}_q \sigma_q \cdot \lambda^{\alpha}_{\bar{q}} \sigma_{\bar{q}}). \quad (8)
\]

Here, $M_0$ is the common $\Sigma_3^+(1S)$ multiplet mass, which depends only upon the chosen diquark ($\delta$, $\delta$) masses and a central potential $V(r)$ computed numerically on the lattice from pure glue configurations that connect 3 and 3 sources, as employed in Ref. 59. The second term represents the spin-spin interaction within diquarks, assumed to couple only $q \leftrightarrow Q$ and $q' \leftrightarrow \bar{Q}$, and $\kappa_Q$ indicates the strength of this interaction. The prime (flavor) index on the light antiquark has been suppressed throughout Eq. (8), since for the moment we consider $q$, $q'$ to be either a light-quark or strange-quark pair, so that the same value of $\kappa_{qQ}$ appears for both spin-spin terms. An isospin-spin-dependent interaction of strength $V_\bar{v}$ between the light-quark spins, which is modeled on the pion-nucleon coupling and was first introduced in Ref. 60, comprises the third term. These 3 terms form the full set included in the analysis of Ref. 60. The final term is new to this work; it is modeled on an $\eta$-nucleon coupling and evaluates in the relevant flavor sectors to:

\[
\Delta M_{V_\bar{v}} = \frac{1}{3} V_\bar{v} \left[ 2s_q q' (s_{q'q} + 1) - 3 \right] \times \begin{cases} 
1, & q, q' \in \{u, d\} \\
4, & q, q' = s, s \end{cases} \quad (9)
\]

To compute the mass expressions arising from Eq. (9), let us first abbreviate

\[
V_- \equiv V_0 - \frac{1}{9} V_\bar{v}, \quad V_+ \equiv V_0 + \frac{1}{3} V_\bar{v}. \quad (10)
\]

Then the Hamiltonian matrix elements for the mixed $\bar{Q}qq'$ states of the $\Sigma_3^+(1S)$ multiplet, their components arranged in the order $s_{Q}q_1q_2$, one obtains

\[
\begin{align*}
M_{I=0}^{I=0} &= (M_0 - \kappa_{qQ} + 3V_-) \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + 2\tilde{V}_1^{Q\bar{Q}qq} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \\
M_{I=1}^{I=1} &= (M_0 - \kappa_{qQ} - V_+) \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + 2\tilde{V}_2^{Q\bar{Q}qq} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \\
M_{I=2}^{I=0} &= (M_0 + 3V_-) \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \tilde{V}_3^{Q\bar{Q}qq} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \\
M_{I=1}^{I=1} &= (M_0 - V_+) \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \tilde{V}_4^{Q\bar{Q}qq} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \\
M_{I=2}^{I=0} &= M_0 - \kappa_{qQ} - 3V_- , \\
M_{I=3}^{I=1} &= M_0 - \kappa_{qQ} + V_+ , \\
M_{I=2}^{I=2} &= M_0 + \kappa_{qQ} - 3V_- , \\
M_{I=3}^{I=3} &= M_0 + \kappa_{qQ} + V_+ ,
\end{align*}
\]

using the abbreviations

\[
\begin{align*}
\tilde{V}_1^{Q\bar{Q}qq} &\equiv \sqrt{\kappa_{qQ}^2 + 3\kappa_{qQ} V_- + 9V_\bar{v}^2}, \\
\tilde{V}_2^{Q\bar{Q}qq} &\equiv \sqrt{\kappa_{qQ}^2 - \kappa_{qQ} V_+ + V_\bar{v}^2}, \\
\tilde{V}_3^{Q\bar{Q}qq} &\equiv \sqrt{\kappa_{qQ}^2 + 36V_-^2}, \\
\tilde{V}_4^{Q\bar{Q}qq} &\equiv \sqrt{\kappa_{qQ}^2 + 4V_\bar{v}^2}. \quad (13)
\end{align*}
\]
B. \(c\bar{c}ss\) Sector

The Hamiltonian relevant to the \(c\bar{c}ss\) sector is identical to the one in Eq. (8), omitting the isospin-dependent \(V_0\) term and performing some \(q \to s\) relabeling,

\[
H = M_0 + \Delta H_{\pi Q} + \Delta H_{\rho Q} + \Delta H_{\eta Q} = M_0 + 2 \kappa_{Q} \left( s \cdot s_Q + s_s \cdot s_Q \right) + V_8 \left( \lambda_8^s \sigma_s \right) \cdot \left( \lambda_8^s \sigma_s \right),
\]

(14)

Equivalently, this expression generalizes the Hamiltonian used in the analysis of Ref. [62] by the inclusion of the \(V_8\) term. Note that the value of \(M_0 = M_Q^{Q \bar{Q} s \bar{s}}\) here differs from \(M_0 = M_Q^{Q \bar{Q} q \bar{q}}\) appearing in Eq. (8). The mass eigenvalues for the 6 isosinglet \(c\bar{c}ss\) states evaluate to

\[
\begin{align*}
M_{0++} &= \left( M_0 - \kappa_{sQ} - \frac{4}{3} V_8 \right) \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + 2 V_1^{QSs} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \\
M_{1+-} &= \left( M_0 - \frac{4}{3} V_8 \right) \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + V_2^{QSs} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \\
M_{1+0} &= M_0 - \kappa_{sQ} + \frac{4}{3} V_8, \\
M_{2++} &= M_0 + \kappa_{sQ} + \frac{4}{3} V_8,
\end{align*}
\]

(15)

where

\[
\begin{align*}
V_1^{QSs} &= \sqrt{\kappa_{sQ}^2 - \frac{4}{3} \kappa_{sQ} V_8 + \frac{16}{9} V_8^2}, \\
V_2^{QSs} &= \sqrt{\kappa_{sQ}^2 + \frac{64}{9} V_8^2}.
\end{align*}
\]

IV. HIDDEN-CHARM, OPEN-STRANGE SECTOR

In this sector, the Hamiltonian analogous to Eq. (8) becomes

\[
H = H_0 + \Delta H_{\pi Q} + \Delta H_{\rho Q} + \Delta H_{\eta Q} = H_0 + 2 \left[ \kappa_{s Q} \left( s_q \cdot s_Q \right) + \kappa_{s Q} \left( s_s \cdot s_Q \right) \right] + V_8 \left( \lambda_8^s \sigma_s \right) \cdot \left( \lambda_8^s \sigma_s \right)
\]

Without loss of generality, we have taken \(q \to s\), with the opposite choice \(q \to s\) simply leading to the antiparticles of those studied here. Then the spin couplings \(\kappa_{sQ}\) and \(\kappa_{Q}\) are numerically quite distinct, and we compute the mass contributions

\[
\Delta M_{\kappa_{Q}} = \frac{1}{2} \kappa_{Q} \left[ 2 s_\delta \left( s_\delta + 1 \right) - 3 \right],
\]

(18)

\[
\Delta M_{\kappa_{sQ}} = \frac{1}{2} \kappa_{sQ} \left[ 2 s_\delta \left( s_\delta + 1 \right) - 3 \right],
\]

(19)

and

\[
\Delta M_{V_8} = -\frac{2}{3} V_8 \left[ 2 s_\delta \left( s_\delta + 1 \right) - 3 \right],
\]

(20)

with the final expression computed in the same manner as is performed to obtain Eq. (0).

A notable feature of the open-strange exotic sector becomes apparent when considering the full \(SU(3)_{\text{flavor}}\) multiplet structure. \(QQ\bar{q}\bar{q}\) states with \(I_3 = 0\) carry good \(J^P\) quantum numbers, and states with different \(J^P\) values of course cannot mix with them. Inasmuch as isospin is a nearly exact symmetry, one can extend \(C\) parity to a full isospin multiplet by defining the conserved \(G\)-parity quantum number (whose eigenvalues for all hadrons are tabulated by the Particle Data Group (PDG) \[7\]). Specifically,

\[
G \equiv (-1)^I C,
\]

(21)

where the \(C\)-parity eigenvalue here is that of the \(I_3 = 0\) member of the isomultiplet. One could generalize the concept of \(G\) parity to a full \(SU(3)_{\text{flavor}}\) multiplet, but since the corresponding flavor symmetry is broken, mixing between the open-strange members of multiplets whose \(I_3 = 0, Y = 0\) members have opposite \(C\) parities can occur. Indeed, this phenomenon is known among the conventional mesons: For example, the strange partners to the lightest \(1^{++}\) and \(1^-\) mesons are named \(K_{1A}\) and \(K_{1B}\) respectively, and the observed \(1^+\) strange-meson mass eigenstates \(K_{1}(1270)\) and \(K_{1}(1400)\) are believed to be nearly equal admixtures of \(K_{1A}\) and \(K_{1B}\) \[7\].

In the exotic sector, the nonstrange \(X_1 (1^{++})\) states cannot mix with \(Z, Z' (1^{+\pm})\) due to \(G\)-parity conservation. However, their open-strange \(1^+\) partners can mix, leading to richer phenomenological possibilities. To wit: The mass expressions obtained from Eq. \[17\], prior to diagonalization, read

\[
\tilde{M}_{0^+} = M_0 \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} - \frac{1}{2} \left( \kappa_{Q} + \kappa_{sQ} \right) \begin{pmatrix} 0 & \sqrt{3} \\ \sqrt{3} & 2 \end{pmatrix} + \frac{2}{3} V_8 \begin{pmatrix} -3 & 0 \\ 0 & 1 \end{pmatrix},
\]

\[
\tilde{M}_{1^+} = M_0 \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \frac{\kappa_{Q}}{2} \begin{pmatrix} -1 & -\sqrt{2} + \sqrt{2} \\ -\sqrt{2} + \sqrt{2} & +1 +1 \end{pmatrix} + \frac{\kappa_{sQ}}{2} \begin{pmatrix} -1 & +\sqrt{2} -\sqrt{2} \\ +\sqrt{2} -\sqrt{2} & +1 +1 \end{pmatrix} - \frac{2}{3} V_8 \begin{pmatrix} 1 & 0 \\ 0 & -3 \end{pmatrix},
\]

\[
M_{2^+} = M_0 + \frac{1}{2} \left( \kappa_{Q} + \kappa_{sQ} \right) - \frac{2}{3} V_8.
\]

(22)

The elements of the matrices for \(0^+\) are again arranged in order of increasing heavy-quark spin. However, those for \(1^+\) are arranged in the order corresponding to increasing mass eigenvalues for their nonstrange partners in the hidden-charm sector: \(X_1, Z, Z'\).

The mass eigenvalues for the \(0^+\) sector read

\[
M_{0^+} = \left[ M_0 - \frac{1}{2} \left( \kappa_{Q} + \kappa_{sQ} \right) + \frac{2}{3} V_8 \right] \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \frac{2}{3} V_1^{QSs} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix},
\]

(23)
where
\[ V_{\bar{Q}Q's}^{Q} = \sqrt{\frac{1}{2} (\kappa_{qQ} + \kappa_{sQ}) + \frac{1}{3} V_{s}^2 + \frac{1}{3} V_{q}^2}. \]  
(24)

The exact expressions for the $1^+$ eigenvalues are of course complicated roots of a cubic equation, but anticipating that $V_{s} \ll \kappa_{qQ} \ll \kappa_{sQ}$, one may perform a perturbative expansion in $V_{s}$ to compute approximate values:
\[ M_{1^+}^{(1)} = M_{0}^{Q}Q's + \frac{1}{2} (-3\kappa_{sQ} + \kappa_{qQ}) + O(V_{s}^2/\kappa_{sQ}), \]
\[ M_{1^+}^{(2)} = M_{0}^{Q}Q's + \frac{1}{2} (\kappa_{qQ} - 3\kappa_{sQ}) + O(V_{s}^2/\kappa_{sQ}), \]
\[ M_{1^+}^{(3)} = M_{0}^{Q}Q's + \frac{1}{2} (\kappa_{sQ} + \kappa_{qQ}) + \frac{2}{3} V_{s} + O(V_{s}^2/\kappa_{sQ}). \]
(25)

V. ANALYSIS

A. Flavor SU(3) Multiplets and Mixing

The original analysis of $c\bar{c}s\bar{s}$ states in Ref. [63], as well as its updated form in Ref. [62], takes the $c\bar{c}s\bar{s}$ states to be completely unmixed with those in the $c\bar{q}q'$ sector, where $q,q' \in \{u,d\}$. If, on the other hand, SU(3)$_{\text{flavor}}$ is exact, then the states should fill octets and singlets of the flavor symmetry. Specifically, the flavor structure of $c\bar{q}q'$ states, now allowing $q,q' \in \{u,d,s\}$, can be discussed using the same framework that applies to conventional $q\bar{q}$ mesons. The $I = 0$, $I_{s} = 0$, $Y = 0$ unmixed octet and singlet combinations are, as usual,
\[ \frac{1}{\sqrt{6}} (u\bar{u} + d\bar{d} - 2s\bar{s}) \quad \text{and} \quad \frac{1}{\sqrt{3}} (u\bar{u} + d\bar{d} + s\bar{s}), \]  
(26)
respectively. In the lightest $(J^{PC} = 0^{-+})$ meson multiplet, these states correspond to $\eta$ and $\eta'$, respectively, which remain largely unmixed because the octet states are pseudo-Nambu-Goldstone bosons whose masses vanish in the chiral limit, while the singlet has a nonzero mass in this limit due to the anomalous breaking of the axial U(1) symmetry of massless QCD.

Heavier meson multiplets, however, support much larger SU(3)$_{\text{flavor}}$ mixing between the octet and singlet combinations. For example, the next-lightest $(1^{-+})$ multiplet features the $\omega$ and $\phi$ as its $I = 0$ states, which appear to be nearly ideally mixed into the flavor combinations $\frac{1}{\sqrt{2}} (u\bar{u} + d\bar{d})$ and $s\bar{s}$, respectively. The appearance of only the $J/\psi\phi$ decay mode for most of the purported $c\bar{c}s\bar{s}$ candidates inspires the implicit adoption of an ideal-mixing ansatz in Refs. [62, 65].

Moreover, the approach of treating $I = 0$ states in the $c\bar{q}q'$ sector as containing no $s\bar{s}$ component, which is implicit in Refs. [59, 60, 62], also introduces a hidden assumption of octet-singlet mixing into the analysis. The fact that $\rho^0 (I = 1$, pure octet) and $\omega (I = 0$, ideally mixed) are nearly degenerate in mass, and likewise for $Z_c(3900)^{0}$ ($I = 1$, pure octet) and $X(3872) (I = 0)$, suggests that substantial octet-singlet flavor mixing is needed to understand the spectrum of both $1^{-+}$ conventional mesons and $\Sigma_{g}^{+}(1S)$ hidden-charm exotic mesons. Isospin symmetry then links the remaining $Y = 0$ states ($\rho^{\pm}$, $Z_c(3900)^{\pm})$. In the case of exotics, the values of $M_{0}^{c\bar{q}q'}$ and $M_{0}^{c\bar{c}s\bar{s}}$ extracted in previous work implicitly incorporate ideal octet-singlet flavor mixing, with strangeness dependence entering only through the differing diquark masses for $\delta = (cq)$ and for $\delta = (cs)$.

In contrast, the value of $M_{0}^{c\bar{c}s\bar{s}}$ for the open-strange ($K$-like) states refers to an unmixed SU(3)$_{\text{flavor}}$ octet. One should therefore not be surprised that simply combining the values of $m_{(cq)}$ from $M_{0}^{c\bar{q}q'}$ and $m_{(cs)}$ from $M_{0}^{c\bar{c}s\bar{s}}$ with the lattice-computed glue potential $V(r)$ between heavy color-triplet sources generates a value for $M_{0}^{c\bar{c}s\bar{s}}$ slightly different from the one that would be obtained from starting with values of $M_{0}$ corresponding to unmixed SU(3)-octet or -singlet $c\bar{c}q'q'$ and $c\bar{c}s\bar{s}$ states. This effect should occur even in the absence of an explicit SU(3)$_{\text{flavor}}$-breaking difference between $m_{\delta = (cq)}$ and $m_{\delta = (cs)}$.

We illustrate this mixing effect using a toy example well known from elementary quantum mechanics: Ignore fine-structure effects and let the unmixed mass parameter $M_{s}$ be pure octet, and $M_{t}$ (pure singlet) degenerate, $M_{s} = M_{t} = M_{s}$, in a 2-level system with an octet-singlet mass-mixing parameter $\Delta$. Then the resulting mass eigenvalues are $M \pm \Delta$, and the mixing angle of the system is maximal, $45^\circ$. More generally, the lower mass eigenvalue is always smaller than the smaller diagonal element, whether or not the unmixed octet and singlet mass parameters are equal. In our case, the value of $M_{0}^{c\bar{c}s\bar{s}}$ from the previous analyses of Refs. [59, 60, 62, 65] is assumed to refer to ideally mixed states; and since one expects the exotics observed thus far (which are used to extract $M_{0}$ values) to be the lightest ones that exist, the derived $M_{0}^{c\bar{q}q'}$ results represent the smaller mass eigenvalues. Meanwhile, $M_{0}^{c\bar{c}s\bar{s}}$ is extracted from states assumed to contain no light valence quarks, and therefore their component diquarks are pure $(cs)$; thus, no mixing needs to be performed to extract the parameter $m_{\delta = (cs)}$. The result for $M_{0}^{c\bar{c}s\bar{s}}$ naively obtained from using the (mixed) $M_{0}^{c\bar{q}q'}$ and $M_{0}^{c\bar{c}s\bar{s}}$ values should therefore be slightly lower than one determined entirely from the pure-octet $c\bar{c}q'q'$ sector. This expectation, in fact, is precisely what occurs, as we see below.

B. $c\bar{c}q'q'$ Sector and $V_{s}$

The analysis of the $c\bar{c}q'q'$ sector here closely follows that of Ref. [60], and especially Ref. [62]. The 3 primary
inputs are the PDG averages \[17\]

\[
\begin{align*}
  m_X(3872) &= 3871.69 \pm 0.17 \text{ MeV}, \\
  m_{Z_c(3900)} &= 3888.4 \pm 2.5 \text{ MeV}, \\
  m_{Z_c(4020)} &= 4024.1 \pm 1.9 \text{ MeV},
\end{align*}
\]

with only the value for \(Z_c(3900)\) changing slightly since the previous analyses. Since the Hamiltonian of Eq. (8) now has 4 parameters, the system is underdetermined. However, one further constraint arises from noting the strong charmonium decay preference \[17\] of \(Z_c(3900)\) to \(J/\psi\) and \(Z_c(4020)\) to \(h_c\), suggesting that these \(Z_c\) states are nearly pure \(s\bar{c}c\) and \(s\bar{c}\bar{c}\) eigenstates, respectively. Defining \(P\) as the \(s_{Q\bar{Q}} = 1\) probability content of the lower-mass \(1^{+}\), \(I = 1\) eigenstate of Eqs. (11) \(i.e.,\) the square of the off-diagonal component of the unitary matrix diagonalizing \(M_{1,1}^{\pm} \) in Eqs. \(11\), one obtains

\[
P = \frac{1}{2} \left[ 1 + \frac{2 \left( V_0 + \frac{\kappa \mu_1}{2} \right)}{\sqrt{\kappa \mu_2^2 + 4 \left( V_0 + \frac{\kappa \mu_1}{2} \right)^2}} \right],
\]

which means that \(V_8\) can be expressed as a function of \(P\) (and the parameters \(V_0\) and \(\kappa \mu_2\)). Using this constraint with the mass expressions in Eqs. (12), the most convenient combinations of the 3 masses in Eqs. (27) are

\[
\begin{align*}
  \mu_1 &= \frac{1}{2} \left( \mu_1 + \mu_3 \right) \\
  &= \frac{1}{2} \left( m_{Z_c(4020)} + m_{Z_c(3900)} \right) = 3956.3 \pm 1.6 \text{ MeV}, \\
  \mu_2 &= \frac{1}{2} \left( \mu_1 - \mu_3 \right) \\
  &= \frac{1}{2} \left( m_{Z_c(4020)} - m_{Z_c(3900)} - m_X(3872) \right) = 84.6 \pm 1.6 \text{ MeV}, \\
  \mu_3 &= \frac{1}{2} \left( m_{Z_c(4020)} - m_{Z_c(3900)} \right) = 67.9 \pm 1.6 \text{ MeV},
\end{align*}
\]

From Eqs. (29), one extracts

\[
\frac{4}{3} m_{V_8} = \frac{\mu_2}{2} + \frac{\mu_3}{2} \left[ \left( P - \frac{1}{2} \right) + \sqrt{P(1 - P)} \right].
\]

The case \(V_8 = 0\), which (in effect) is imposed in Ref. \(62\), becomes

\[
P = \frac{1}{4} \left[ 2 + \left( \frac{\mu_2}{\mu_3} \right)^2 \right],
\]

\[
= 0.979 \pm 0.009, \ 0.644 \pm 0.030.\]

In fact, Eq. (30) places a rather strong constraint upon \(V_8\). While any \(P \in [0, 1]\) is in principle allowed, values of \(P\) smaller (larger) than the smaller (larger) root in Eq. (31) lead to negative values of \(V_8\) and, for sufficiently small values of \(P\), values of \(V_4\) that are also larger in magnitude than \(V_4\). Inasmuch as the accompanying operators in Eq. (8) represent \(\pi\)-like and \(\eta\)-like exchanges, respectively, one expects the analogy to the dynamics of true \(\pi\) and \(\eta\) exchanges between nucleons \(i.e.,\) chiral perturbation theory) to hold. Under this assumption, the \(\eta\)-like exchange should be attractive like the \(\pi\)-like exchange; hence \(V_8\), like \(V_0\), should be positive. However, genuine \(\eta\) exchange is also weaker than \(\pi\) exchange, both due to the \(\eta\)’s larger mass and larger decay constant. We therefore take \(V_8 > 0\) to be a natural constraint of the model, which requires \(P\) to lie between the roots given in Eq. (31). According to Eq. (30), within this range \(V_8\) reaches a maximum at \(P = \frac{1}{2}\left( 1 + \frac{\sqrt{2}}{\sqrt{2}} \right) = 0.854\), at which

\[
V_8^{\text{max}} = \frac{3}{4} \left( -\mu_2 + \sqrt{2} \mu_3 \right) = 8.6 \pm 2.3 \text{ MeV}.
\]

We therefore expect the allowed range of \(V_8\), as determined by the known phenomenology of the \(c\bar{c}q\bar{q}'\) sector, to have a modest effect compared to that provided by the other parameters in Eq. (8). Using Eqs. (29), one obtains for the other Hamiltonian parameters:

\[
\begin{align*}
  M_0 &= \mu_1 + \left( P - \frac{1}{2} \right) \mu_3, \\
  \kappa \mu_2 &= 2 \mu_3 \sqrt{P(1 - P)}, \\
  4V_0 &= \mu_2 + 2 \mu_3 \left[ \left( P - \frac{1}{2} \right) - \sqrt{P(1 - P)} \right].
\end{align*}
\]

The values of \(M_0, \kappa \mu_2,\) and \(V_0\) obtained for both \(V_8 = 0\) and for an optimized \(V_8\) value obtained below from the \(c\bar{c}s\bar{s}\) spectrum \(\text{[in Eqs. (45)]}\) are presented in Table I. The full spectrum of masses for the \(c\bar{c}q\bar{q}'\) \(\Sigma_{1}^{+}(1S)\) multiplet appears in Table II.

Using the value of \(M_0^{c\bar{c}q\bar{q}'}\) from Table I with \(V_8 = 0\) and the lattice-simulated glue potentials \(V(\bar{r})\) of Refs. \(66, 67\) (JKM) and \(68\) (CPRRW), we compute

\[
m_{\delta(cq)} = 1938.5 \pm 0.8 \text{ MeV (JKM)},
\]

\[
= 1915.5 \pm 0.8 \text{ MeV (CPRRW)}.
\]

A value spanning this spread is presented in Table II. Again, these results for \(V_8 = 0\) differ from those in Ref. \(62\) only through a small shift in the tabulated PDG value of \(m_{Z_c(3900)}\) in Eq. (27).

C. \(c\bar{c}s\bar{s}\) Sector: \(\kappa \mu_2\) and \(V_8\)

The signature process used in Ref. \(62\) to identify \(c\bar{c}s\bar{s}\) exotics is the decay mode \(J/\psi \phi\), although some candidates are identifiable through \(D_{s}\)-type meson-pair decays. Furthermore, the analysis of Ref. \(62\) argues that the \(J^{PC} = 1^{++}\) \(X(4274)\) is an excellent candidate for
the conventional charmonium state $\chi_{c1}(3P)$. The most unexpected addition to the $c\bar{c} s\bar{s}$ spectrum is the peculiar state $X(3915)$, with likely $0^{++}$ quantum numbers, as the candidate for the lightest $c\bar{c} s\bar{s}$ state in this model. In brief summary of the reasoning in Ref. [65] and references therein, $X(3915)$ has no confirmed open-charm decays, thus arguing against it being either the conventional charmonium state $\chi_{c2}(2P)$ or $c\bar{c} q q$. It has definitively been seen to couple only to $\gamma \gamma$ and $J/\psi \omega$; with respect to the latter mode, note that $X(3915)$ lies below the $J/\psi \phi$ threshold, so that $\phi \rightarrow \omega$ mixing is proposed in Ref. [66] to be responsible for the $J/\psi \omega$ decay mode. Furthermore, a recent lattice calculation [69] predicts the existence of a $0^{++}$ state in this mass region that has a strong coupling to $D_s \bar{D}_s$ but a weak coupling to $D \bar{D}$. The mass used in this work is the PDG value [17]:

$$m_{X(3915)} = 3921.7 \pm 1.8 \text{ MeV}. \quad (35)$$

In the previous analysis [62], the $c\bar{c} s\bar{s}$ spectrum obtained for the multiplet is very simple. Referring to Eqs. [15], the assumption that $\kappa_{sc} > V_8 > 0$ leads to the spectrum (in increasing order of mass):

$$
\begin{align*}
M_{0^{0+}} &= M_0 - 3\kappa_{sc} + O(V_8^2/\kappa_{sc}), \\
M_{1^{+-}} &= M_0 - \kappa_{sc} - \frac{4}{3}V_8 + O(V_8^2/\kappa_{sc}), \\
M_{1^{++}} &= M_0 - \kappa_{sc} + \frac{4}{3}V_8, \\
M_{0''^{++}} &= M_0 + \kappa_{sc} - \frac{8}{3}V_8 + O(V_8^2/\kappa_{sc}), \\
M_{1'^{+-}} &= M_0 + \kappa_{sc} - \frac{4}{3}V_8 + O(V_8^2/\kappa_{sc}), \\
M_{2^{++}} &= M_0 + \kappa_{sc} + \frac{4}{3}V_8, \quad (36)
\end{align*}
$$

which reduces to 3 degenerate sets in the case $V_8 = 0$, as listed in Ref. [62]. In particular, the lighter $0^{++}$ state clearly lies far below the others, with the $1^{++}$ state (and the lighter $1^{-+}$) being intermediate in mass, and the $2^{++}$ and heavier $0^{++}$ (and $1^{+-}$) states lying close together at a larger mass value. The overall effect of Eq. (36) is to split the $\Sigma_{c}^{+}(1S)$ multiplet into 3 roughly equally spaced (by $2\kappa_{sc}$) clusters of $c\bar{c} s\bar{s}$ states.

The state $X(4140)$ is taken to be an unmistakable $c\bar{c} s\bar{s}$ candidate, the sole $1^{++}$ member of the multiplet $\Sigma_{c}^{+}(1S)$. Therefore, the $c\bar{c} s\bar{s}$ spectrum should start with $X(3915)$ being the distinct lightest member, a $1^{++}$ state is predicted to appear with a mass near $m_{X(4140)}$, and a trio of states ($0^{++}$, $1^{+-}$, $2^{++}$) is predicted to appear at approximately $m_{X(3915)}^2 + 2(m_{X(4140)} - m_{X(3915)})$. A complication arises, however, with the latest LHCb measurement [7] of $X(4140)$:

$$
\begin{align*}
&m_{X(4140)} = 4118 \pm 11^{+36}_{-39} \text{ MeV}, \\
&\Gamma_{X(4140)} = 162 \pm 21^{+24}_{-49} \text{ MeV}, \quad (37)
\end{align*}
$$

which should be compared to the PDG average [17],

$$
\begin{align*}
&m_{X(4140)} = 4146.8 \pm 2.4 \text{ MeV}, \\
&\Gamma_{X(4140)} = 22^{+8}_{-7} \text{ MeV}, \quad (38)
\end{align*}
$$

the mass differing by about $1.3\sigma$ (and the width differing radically). LHCb observes $X(4140)$ with a $13\sigma$ total significance.

In fact, the data used in Ref. [70] forms a small subset of the LHCb data reported in Ref. [5]. So how can a measurement using much more data lead to a result with much larger uncertainties? In large part, it arises from a new modeling of the $X(4140)$ lineshape, in which a naive Breit-Wigner profile is replaced with a Flatté form [71]. To incorporate this new development, we reanalyze the PDG mass average of Eqs. (38) by replacing the old LHCb mass measurement of Eqs. (39) with the new one of Eqs. (37), producing the value to be used in our analysis:

$$
\begin{align*}
&m_{X(4140)} = 4146.7 \pm 2.7 \text{ MeV}. \quad (40)
\end{align*}
$$

The state $X(4350)$, although not yet confirmed at the same level of confidence ($3.2\sigma$), is seen in $\gamma \gamma \rightarrow J/\psi \phi$ and thus is an excellent $c\bar{c} s\bar{s}$ $0^{++}$ or $2^{++}$ candidate. Noting that [17]

$$m_{X(4350)} = 4351 \pm 5 \text{ MeV}, \quad (41)$$

and using Eqs. [36] and [40], one finds

$$
\begin{align*}
m_{X(3915)} + 2(m_{X(4140)} - m_{X(3915)}) &= 4371.7 \pm 5.7 \text{ MeV}. \quad (42)
\end{align*}
$$

| \begin{align*} \nu_{8} = 0 \\ \nu_{8} = 3.9 \pm 1.4 \text{ MeV} \end{align*} | \begin{align*} M_{0}^{c\bar{c} q q'} \\ \kappa_{qc} \\ V_{0} \\ P \\ m_{\delta(cq)} \\ M_{0}^{c\bar{c} q} \\ \kappa_{sc} \\ m_{\delta(cs)} \\ M_{0}^{c\bar{c} q'q} \end{align*} |
|---|---|
|---|---|
|---|---|
One then sees (as in Refs. [62, 63]) that $X(4350)$ nearly satisfies the equal-spacing rule discussed above, which confirms our previous result that $V_8$ is numerically small. In fact, at linear order in $V_8$, Eqs. (36) give

$$\begin{align*}
(M'_{0++} - M_{1++}) - (M_{1++} - M_{0++}) &= -\frac{16}{3} V_8, \\
(M_{2++} - M_{1++}) - (M_{1++} - M_{0++}) &= \frac{4}{3} V_8.
\end{align*}$$

Using $m_X(4350)$ from Eq. (41) for $M'_{0++}$ or $M_{2++}$ gives

$$\begin{align*}
(m_X(4350) - m_X(4140)) - (m_X(4140) - m_X(3915)) &= -20.7 \pm 7.6 \text{ MeV},
\end{align*}$$

meaning that $V_8$ is small and positive, as anticipated in Eq. (32). Returning to the full mass expressions of Eqs. (15), one uses Eqs. (35), (40), and (41) to obtain

$$\begin{align*}
M_0^{c\bar{c}s\bar{s}} &= 4251.3 \pm 2.8 \text{ MeV}, \\
\kappa_{sc} &= 109.8 \pm 1.1 \text{ MeV}, \\
V_8 &= 3.9 \pm 1.4 \text{ MeV},
\end{align*}$$

assuming that $X(4350)$ is $0^{++}$, and

$$\begin{align*}
M_0^{c\bar{c}s\bar{s}} &= 4230.8 \pm 7.0 \text{ MeV}, \\
\kappa_{sc} &= 102.2 \pm 2.8 \text{ MeV}, \\
V_8 &= 13.6 \pm 4.3 \text{ MeV},
\end{align*}$$

assuming that $X(4350)$ is $2^{++}$. Obtaining these results requires the resolution of a discrete ambiguity to impose the physical expectation $\kappa_{sc} > 0$, as discussed in Ref. [62]. The latter solution produces a slightly larger value of $V_8$ than allowed by Eq. (32), but only by $1.0\,\sigma$, and therefore still viable. Nevertheless, for purposes of illustration, we choose Eqs. (45) as the best-fit parameters (also included in Table I), and use them to compute the full spectrum of masses for the $\Sigma^+_q(1S)$ $c\bar{c}s\bar{s}$ multiplet in Table II.

In particular, using the value of $M_0^{c\bar{c}s\bar{s}}$ from Eqs. (45) and the lattice-simulated glue potentials $V(r)$ of Refs. [66-68], we compute

$$m_{\delta(cs)} = 2080.2 \pm 1.5 \text{ MeV} (\text{JKM}),$$

$$= 2058.5 \pm 1.5 \text{ MeV} (\text{CPRRW}).$$

The $M_0^{c\bar{c}s\bar{s}}$ and $\kappa_{sc}$ values obtained in Eqs. (45) and (47) differ rather little from those in Ref. [62], in part because the previous work effectively takes $V_8 = 0$, and also because the inputs of Eqs. (35) and (40) have changed little in the interim.

Feeding the value of nonzero $V_8$ back into the $c\bar{c}q\bar{q}$' expressions given by Eqs. (30) and (33), one obtains the $V_8 > 0$ values of $M_0^{c\bar{c}q\bar{q}}$, $\kappa_{qc}$, $V_0$, and $P$ given in Table II.

Using this value of $M_0^{c\bar{c}q\bar{q}}$ and the lattice-simulated glue potentials $V(r)$ of Refs. [66-68], we compute

$$m_{\delta(qc)} = 1938.0 \pm 0.9 \text{ MeV} (\text{JKM}),$$

$$= 1916.2 \pm 0.9 \text{ MeV} (\text{CPRRW}).$$

The averaged values for Eqs. (47) and (48) appear in Table II.

### D. $c\bar{c}q\bar{q}$ Sector

The results obtained from the $c\bar{c}q\bar{q}$ and $c\bar{c}s\bar{s}$ $\Sigma^+_q(1S)$ multiplets in the previous two subsections, with parameters collected in Table II, are almost completely sufficient to predict the entire $c\bar{c}q\bar{q}$ $\Sigma^+_q(1S)$ spectrum. However, as noted in Sec. [5A], the fact that the open-strange states are pure SU(3)$_W$ flavor octet, while $c\bar{c}q\bar{q}$ and $c\bar{c}s\bar{s}$ are assumed to be ideally mixed octet-singlet combinations, means that the value of $M_0^{c\bar{c}q\bar{q}}$ extracted using only inputs from the other sectors is likely to be slightly too low to match observed $Z_{cs}$ masses in Eqs. (2). On the other hand, the fine structure obtained in this sector using values of $\kappa_{sc}$, $\kappa_{qg}$, and $V_8$ from Table II should be predicted correctly.

Explicitly, using the $m_{\delta(qc)}$ from Eqs. (48), $m_{\delta(cs)}$ from Eqs. (47), and the same lattice-calculated glue potentials $V(r)$ as used previously, we compute

$$M_0^{c\bar{c}q\bar{q}} = 4119.7 \pm 1.7 \text{ MeV} (\text{JKM}),$$

$$= 4119.7 \pm 1.7 \text{ MeV} (\text{CPRRW}),$$

a remarkably stable result across simulations. Using this value along with the other parameters in Table II in the $1^+$ expressions of Eqs. (22), we compute

$$m_{Z_{cs}^{(1)}} = 3967.7 \pm 3.4 \text{ MeV},$$

$$m_{Z_{cs}^{(2)}} = 4136.0 \pm 7.1 \text{ MeV},$$

$$m_{Z_{cs}^{(3)}} = 4190.3 \pm 3.1 \text{ MeV},$$

which are lower than the measured values given in Eqs. (2). If, however, we add an offset

$$\Delta M_0^{c\bar{c}q\bar{q}} = 35.3 \pm 6.9 \text{ MeV},$$

then the predictions of Eqs. (50) become

$$m_{Z_{cs}^{(1)}} = 4003.0 \pm 7.6 \text{ MeV},$$

$$m_{Z_{cs}^{(2)}} = 4171.3 \pm 10.3 \text{ MeV},$$

$$m_{Z_{cs}^{(3)}} = 4225.6 \pm 7.5 \text{ MeV},$$

and so $m_{Z_{cs}^{(1)}}$ and $m_{Z_{cs}^{(3)}}$ beautifully match the observed values in Eqs. (2).

Of course, this model predicts also a third open-strange $1^+$ state $Z_{cs}^{(2)}$, which is not, as yet, reported by LHCb. In this regard, we note that the reported mass uncertainty and width of $Z_{cs}(4220)$ in Eqs. (2) are quite large, meaning that subsequent analysis might resolve the peak as two states $Z_{cs}^{(2)}$ and $Z_{cs}^{(3)}$, as was found for the pentaquark candidates $P_{c}(4440)$ and $P_{c}(4457)$ in Ref. [72]. Small hints of additional structure may be already visible in the LHCb results above 4100 MeV (Fig. 3 of [72], right inset). The relative closeness of $Z_{cs}^{(2)}$ and $Z_{cs}^{(3)}$ in mass follows directly in this model, as can be seen from Eqs. (25), since (Table II), $\kappa_{qc} \ll \kappa_{sc}$. The large mass splitting $m_{Z_{cs}^{(3)}} - m_{Z_{cs}^{(1)}} \approx 2 \kappa_{sc} > 200 \text{ MeV}$ is also explained naturally by the model; in this regard, note that such a
large mixing would not have occurred without the mixing of strange states between $1^{++}$ and $1^{-+}$ multiplets, as discussed in Sec. LV.

One other criterion may be useful for disentangling the trio of $1^{+}$ states $Z_{cs}^{(1)}$. The eigenvectors of Eqs. (22) couple differently to the heavy- and light-quark-spin eigenstates $X_1$ [Eqs. (6)], $Z'$, and $Z$ [defined in Eqs. (7)]. Explicitly, in the limit $V_8 = 0$, the corresponding eigenvectors with respect to this basis are

$$
u_{(1),(2),(3)} = \frac{1}{2} \left( \begin{array}{c} \sqrt{2} \\ -1 \\ 1 \end{array} \right), \quad \frac{1}{2} \left( \begin{array}{c} -\sqrt{2} \\ -1 \\ 1 \end{array} \right), \quad \frac{1}{\sqrt{2}} \left( \begin{array}{c} 0 \\ 1 \\ 1 \end{array} \right).$$

Since only $Z$ has $s_{QQ} = 0$, the third component of each eigenvector indicates the relative strength of the coupling to $h_c$ (vs. $J/\psi$) in decays that conserve heavy-quark spin.

We note that $Z_{cs}^{(2)}$ has the largest such coupling: 50% of its decays should be to $s_{QQ} = 0$ states. Therefore, a prediction of this model is not only that $Z_{cs}^{(4220)}$ resolves into two peaks, but also that the lower state couples particularly strongly to $h_c$.

Using the values of $M_0^{ccqs}$, $\kappa_{cr}$, $\kappa_{qc}$, and $V_8$ from Table I and the shifted multiplet average mass [using Eq. (51)],

$$M_0^{ccqs} = M_0^{ccqs} + \Delta M_0^{ccqs} = 4155.0 \pm 7.5 \text{ MeV},$$

we tabulate mass values for all members of the $\Sigma^+_c(1S)$ $ccqs$ multiplet in Table II.

### E. The $ccuds$ Pentaquark

The numerical analysis of Ref. [59] builds upon the proposal of pentaquarks as diquark-triquark bound states [57], where the triquark $\bar{\theta}$ is formed using a concatenation of the same color-triplet-binding mechanism as appears within the diquarks:

$$\bar{\theta} = [Q(q_1 q_2) q_3].$$

The dynamical diquark model then uses the same lattice-calculated potentials as before [56,58] to connect the diquark and triquark quasiparticles. In the original calculations of Ref. [59], the pentaquark candidates $P_c(4312)$, $P_c(4380)$, $P_c(4440)$, and $P_c(4457)$ observed at LHCb [72,73] are considered as $\delta = (cu)$, $\bar{\theta} = [\bar{c}(ud)]$ bound states using a coarse analysis: LHCb identifies $P_c(4380)$ as having opposite parity to $P_c(4440)/P_c(4457)$ [72] and such a small splitting between multiplets of opposite parity in the model makes sense only if $P_c(4380)$ is a high-lying state in the $P = -\text{multiplet } \Sigma^+(1S)$ [$J^P = (\frac{1}{2}, \frac{3}{2})^-$], while the other states belong to the $P = +\text{ multiplet } \Sigma^+(1P)$ [$J^P = (\frac{1}{2}, \frac{3}{2})^+]$.

Using $P_c(4312)$ to fix $M_0$ for the $\Sigma^+(1P)$ multiplet, where

$$m_{P_c(4312)} = 4311.9 \pm 6.8 \text{ MeV},$$

and using $m_{\delta = (cq)}$ obtained from the $ccqq'$ states, Ref. [59] computes a value of $m_{\bar{\theta}} \approx 1.93 \text{ GeV}$. Repeating the analysis here using the new value of $m_{\bar{\theta} = (cq)}$ from Eq. (48), we find

$$m_{\bar{\theta} = (cq,q_2)} = 1884.6 \pm 7.5 \text{ MeV (JKM)},$$

$$= 1865.5 \pm 7.5 \text{ MeV (CPRRW)}.$$

As noted in Ref. [59], $m_{\delta = (cq)}$ and $m_{\bar{\theta} = (cq,q_2)}$ are quite close in mass; indeed, $m_{\bar{\theta}}$ is actually slightly smaller than $m_4$ in the new calculation. This peculiarity arises from assigning the lowest observed $ccqq'$ states to the ground-state $\Sigma^+_c(1S)$ multiplet but assigning the lowest observed pentaquark $P_c(4312)$ to the excited $\Sigma^+_c(1P)$ multiplet. Should the opposite-parity $P_c(4380)$ disappear from future data, then $P_c(4312)$ and the other states would become suitable to belong to $\Sigma^+_c(1S)$, and $m_{\bar{\theta}}$ (absorbing what was orbital excitation energy) would become numerically larger. Even in the current circumstance, however, no obvious physical requirement demands that $m_\theta > m_\delta$. Indeed, one may argue that $\bar{\theta}$ contains two significant sources of binding energy: within the diquark $(q_1 q_2)$, and between this diquark and $\bar{c}$, while $\delta$ possesses only the first type of binding, thereby allowing $m_{\bar{\theta}} \lesssim m_\delta$.

Now suppose that the state $P_{cs}(4459)$ of Eqs. (3) is the open-strange $\Sigma^+_c(1P)$ analogue to $P_c(4312)$, i.e., a $\delta$-$\bar{\theta}$ state with $\delta = (cs)$, where $m_\delta = (cs)$ is given in Eqs. (47). Then we compute

$$M_0^{ccqs,q_2} = 4441.8 \pm 7.0 \text{ MeV (JKM)},$$

$$= 4441.7 \pm 7.0 \text{ MeV (CPRRW)}.$$

This is a stunning result, being less than 2σ lower than the value in Eqs. (3). Indeed, no reason apart from convenience leads one to take the $P_c(4312)$ [as opposed to, say, $P_c(4457)$] and $P_{cs}(4459)$ masses equal to the $M_0$ values for their respective $\Sigma^+_c(1P)$ multiplets, except that they are the lightest ones known. A complete analysis would incorporate fine structure, as is done for the tetraquark sectors, but this exercise has not yet been carried out in the pentaquark sectors of this model, due to a lack of experimental clarity on $J^P$ quantum numbers for at least some of the observed states. Nevertheless, the result of Eqs. (58) shows that a single model can, in fact, accommodate exotics in all observed flavor sectors.

The development of the dynamical diquark model to date has focused primarily on spectroscopy, and to a

---

[3] It is actually the original, unresolved $P_c(4450)$ of Ref. [73] that has opposite parity to $P_c(4380)$, and an assumption of this work that the two resolved components $P_c(4440)$ and $P_c(4457)$ [72] share this same parity eigenvalue.

[4] The $g$ quantum number is lost in the asymmetric diquark-triquark case [58].
TABLE II. Predictions of hidden-charm plus light-quark tetraquark meson masses (in MeV) for all states in the lowest multiplet \( \Sigma \) of the dynamical diquark model, using the Hamiltonian parameters of Table I and Eq. (54) for \( ccqs \). Observed masses (used to obtain the Hamiltonian parameters) are exhibited in boldface. Uncertainties are obtained by including those on all fit parameters.

| \( J^{PC} \) | \( ccq\bar{q} \) | \( c\bar{c}s\bar{s} \) | \( c\bar{c}q\bar{s} \) |

| 2\( ^{++} \) | \( 3923.4 \pm 7.8 \) \( \ldots \) | \( 4045.0 \pm 5.6 \) \( \ldots \) | \( 4366.3 \pm 3.5 \) \( \ldots \) |

lesser extent on identifying the dominant quarkonium decay channels. Detailed quantitative calculations of strong decay widths, particularly for open-heavy-flavor channels, have not yet been attempted, because a precise description of couplings between diquark and hadron-hadron configurations has not yet been developed. Qualitative statements to explain the relative narrowness of exotic states have appeared since the initial description of the picture in Refs. [56, 67]; they originate from the significant spatial separation between the diquark or triquark quasiparticles, which hinders the rearrangement of their component quarks into color-singlet hadrons. Such effects may need to be quite potent in the pentaquarks, since \( P_c(4312), P_c(4440), P_c(4457), P_{cs}(4459) \) all have surprisingly small widths (\( \lesssim 20 \) MeV). In addition, the proximity of these states to \( D^{(*)}\bar{D}^{(*)} \Sigma^+_c^0 \) or \( D^{(*)}\bar{D}^{(*)} \Xi_c^+ \) thresholds has been noted since the original experimental papers, and predicted earlier in molecular models [74, 77]. The next phase of the development of the model will address the effect of mixing between diquark configurations and hadron-hadron thresholds, thus providing critical insight into both the decay properties of exotics and a connection to the successes of hadronic-molecule pictures.

VI. CONCLUSIONS

This work shows that the newly observed hidden-charm, open-strange exotic-hadron candidates \( Z_{cs}(4000), Z_{cs}(4220), \) and \( P_{cs}(4459) \) fit naturally into the dynamical diquark model. Notably, the same lattice-simulated potential \( V(r) \) between two heavy, color-triplet sources in the lowest Born-Oppenheimer configuration \( \Sigma^+_c^0 \) is seen to apply to all cases studied here.

Among tetraquarks, the same Hamiltonian parameters, with numerical values obtained from the \( ccq\bar{q} \) \( (q, q' \) being \( u \) or \( d \)) and \( c\bar{c}s\bar{s} \) exotic \( \Sigma^+_g(1S) \) multiplets, successfully predict masses in the \( ccqs \) sector. In particular, the large \( Z_{cs}(4220)-Z_{cs}(4000) \) mass splitting emerges naturally as consequences of both the large \( (cs) \) diquark internal spin-spin coupling \( n_{sc} \) and the mixing of open-strange members of \( J^{PC} = 1^{++} \) and \( 1^{+-} \) multiplets, the latter an effect seen in conventional hadron physics for strange mesons such as \( K_{1A} \) and \( K_{1B} \). The model also predicts a third \( 1^{++} Z_{cs} \) state lying not far below \( 4200 \) MeV.

The overall multiplet-average mass \( M_0 \) for \( ccqs \) states also receives a shift modification compared to those for \( ccq\bar{q} \) and \( c\bar{c}s\bar{s} \) states, since the former are pure SU(3)\_flavor octet states, while states in the latter sets are assumed in the numerical analysis to be ideally mixed octet-singlet combinations. The size of this shift \( \Delta M_0^{ccqs} \) is found to be numerically not large, at most a few 10's of MeV.

In addition, the model in all sectors has been expanded to allow not only a \( \pi \)-like interaction operator between the diquarks (as in previous studies), but an \( \eta \)-like interaction operator as well. The numerical size of the coefficient \( V_q' \) of this operator is found to be much smaller than that \( (V_\pi) \) for \( \pi \)-like interactions, and has a fairly minimal effect on the hadron spectra. Mass predictions for all states in the \( \Sigma^+_g(1S) \) multiplet for each flavor content are presented.

Among pentaquarks, a crude calculation taking the nonstrange \( P_c(4312) \) as a base state for the positive-parity multiplet \( \Sigma^+(1P) \) constructed of a diquark-triquark pair \( (cq)\bar{c}(ud) \), and replacing the \( (cq) \) diquark with a \( (cs) \) diquark, produces a state very close in mass to that of \( P_{cs}(4459) \).

As new exotic hadrons continue to be uncovered—a rather safe expectation, considering the rate of observational advances over the past few years—more opportunities for sharpening our understanding of their mass spectrum and transitions will emerge. Whether or not a diquark-based spectrum provides the eventual global picture for these states, the dynamical diquark model supplies a definite road map for the sort of spectrum to expect.
