We explore signals of lepton-number-violation in the charm physics sector. We study the four-body $|\Delta L| = 2$ decays of the $D^0$ meson, $D^0 \to P^− π^− μ^+ μ^+$ ($P = \pi, K$) as an alternative evidence of the Majorana nature of neutrinos. We carry out an exploratory study on the potential sensitivity that LHCb experiment could achieve for these $|\Delta L| = 2$ processes. We show that for a long term expected integrated luminosity of 300 fb$^{-1}$, a signal significance of branching ratios of the order $O(10^{-9})$ might be accessible, allowing to improve the experimental bounds obtained by the E791 experiment. Limits on the parameter space of a heavy sterile neutrino that could be obtained from their experimental search are discussed as well.

I. INTRODUCTION

Looking for lepton-number-violating (LNV) signals in neutrinoless double-$\beta$ ($0\nu\beta\beta$) nuclear decay is considered as the most attractive and sensitive way to prove that neutrinos are their own antiparticles (or not), i.e. elucidate if neutrinos are Majorana particles (or Dirac ones) [1–4]. Nowadays, the experiments Majorana, GERDA, CUORE, EXO-200 and KamLAND-Zen [5–9] have reported the best lower limits on the half-lives of different isotopes ($^{76}\text{Ge}, ^{130}\text{Xe}, ^{130}\text{Te}$) that typically leads to $T_{1/2} \gtrsim 10^{25}$ yr. Despite all these experimental effort, the lack of evidence of this $|\Delta L| = 2$ process opens the possibility of pursuing different low-energy search pathways as alternative evidence to test the Majorana nature of neutrinos. This complementarity is also reinforced by the fact that a positive observation of $0\nu\beta\beta$ decay can only probe the first fermion family (LNV ee sector), while alternative LNV searches are accessible to different leptonic sectors [2].

Since their experimental search is accessible to different flavor facilities, the low-energy studies of $|\Delta L| = 2$ decays of pseudoscalar mesons $K, D, D_s, B, B_c, B_s$ (both charged and neutral) and the $\tau$ lepton have attracted a lot of theoretical attention [10–40], where different final-state topologies have been considered. An interesting way of realizing these $|\Delta L| = 2$ decays is through the exchange of an intermediate on-shell Majorana neutrino $N$ with a kinematically allowed mass (typically, hundreds of MeV up to few GeV), leading to a considerably enhancement of the decay rates [10, 13–40]. In Refs. [41, 42] have found that the $0\nu\beta\beta$ rate can also be enhanced due to the contribution from heavy neutrino exchange with masses in the GeV scale. Interestingly enough, new physics scenarios with heavy Majorana neutrinos within this GeV mass range have been investigated as a simultaneous explanation to the neutrino mass generation and the baryon asymmetry of the Universe (via leptogenesis) [43–47].

Experimentally, upper limits (UL) on the branching ratios of various of these $|\Delta L| = 2$ decays have been obtained by the experiments NA48/2, E865, BABAR, Belle, LHCb, and E791 [48–57]. See also the Particle Data Group [58]. In Fig. 1, we present a summary of the current UL for different three- and four-body channels. The strongest limits come from kaon sector, particularly from the channel $\text{BR}(K^- \to π^− μ^− μ^-) < 8.6 \times 10^{-11}$ [48]; while in the heavy flavor sector, the channel $\text{BR}(B^- \to π^+ μ^- μ^-) < 4.0 \times 10^{-9}$ [54] provides the strongest one. A long term integrated luminosity of 300 fb$^{-1}$ is expected in future LHCb upgrade, and whereas for Belle II, a 50-fold increase in integrated luminosity is expected greater than previous record (Belle and BABAR), allowing to improve the sensitivity on the $|\Delta L| = 2$ channels. Perspectives on the experimental sensitivity of the NA62 experiment to searches of heavy neutrinos has been discussed as well [59]. Furthermore, recent studies show the sensitivity of the LHCb and CMS experiments to look for LNV signals in $|\Delta L| = 2$ processes of $Λ_b$ baryon and $B_s$ meson [39, 60].

Regarding LNV searches in the charm physics, the LHCb collaboration found 90% confidence level limits on the branching ratios of the three-body decays $\text{BR}(D^+ \to π^− μ^+ μ^-) < 2.2 \times 10^{-8}$ and $\text{BR}(D^+_s \to π^+ μ^- μ^+) < 1.2 \times 10^{-7}$ [53], that improve by several orders of magnitude the previous limits obtained by BABAR [50]. While, the four-body channels $D^0 \to h^- h^+ ℓ^− ℓ'^+$, where $h, h' = π, K$ and $ℓ, ℓ' = e, μ$, were studied by the E791 collaboration [57] more than a decade ago and 90% confidence level upper limits of order $O(10^{-5}−10^{-4})$ for their branching ratios were obtained. Currently, the LHCb experiment has collected the largest sample of charmed mesons and supplementary searches of $|\Delta L| = 2$ channels could be performed, thus complementing previous LHCb analysis [52–54].

Our aim in this work is to explore a charmed search to track the possible LNV signals at the LHCb experiment by studying the four-body $|\Delta L| = 2$ decays of the $D^0$ meson, $D^0 \to P^- π^− μ^+ μ^+$ ($P = π, K$). Their search will provide an alternative evidence of the Majorana nature of neutrinos, allowing to prove the LNV
eral orders of magnitude the experimental limits obtained at the LHCb experiment will be able to improve by several orders of magnitude. We carry out an exploratory study on the potential sensitivity that LHCb experiment could achieve for these processes \([10, 15, 20]\). We will consider a simplified approach in which one heavy Majorana neutrino \(N\), with a kinematically allowed mass in the range \(m_N \in [0.25, 1.62]\) GeV such that it can be produced on-shell in these processes, dominates the decay amplitude. These four-body \(|\Delta L| = 2\) channels have been previously studied in Refs. \([25–27]\) using different approaches for the evaluation of the hadronic transition \(D \to P\). Taking the UL reported by E791 experiment \([57]\), in Ref. \([25]\) obtained bounds on the parameters space of a heavy neutrino \((m_N, |V_{\mu N}|^2)\) that turned out to be very mild. Moreover, the authors of Ref. \([26]\) estimated from 2.9 fb\(^{-1}\) Monte Carlo sample that BESIII experiment could get an UL on the channel \(D^0 \to K^-\pi^+\pi^+\) of the order \(1 \times 10^{-9}\); nevertheless, such a sensitivity is far below the one obtained from \(0\nu\beta\beta\) decay. Here, we present a reanalysis of these \(|\Delta L| = 2\) channels by considering the recent lattice QCD calculations of the semileptonic \(D \to P\) form factors \([61]\). We pay particular attention to the \(\mu^+\mu^+\) channels and their experimental signal at the LHCb experiment (see Sec. III).

The branching fraction of the four-body \(|\Delta L| = 2\) decays \(D^0 \to P^-\pi^-\mu^+\mu^+\) can be written in the factorized form

\[
B(D^0 \to P^-\pi^-\mu^+\mu^+) = B(D^0 \to P^-\mu^+) \times \Gamma(N \to \mu^+\pi^-)\tau_N/\hbar,
\]

where the on-shell Majorana neutrino is produces through the semileptonic decay \(D^0 \to P^-\mu^+N\) and consecutively \(N \to \mu^+\pi^-\), with \(\tau_N\) as the lifetime of the Majorana neutrino. The decay width of \(N \to \mu^+\pi^-\) is given by the expression \([10]\)

\[
\Gamma(N \to \mu^+\pi^-) = |V_{\mu N}|^2 \tilde{\Gamma}(N \to \mu^-\pi^+),
\]

with

\[
\tilde{\Gamma}(N \to \mu^+\pi^-) = \frac{G_F^2}{16\pi} |V_{ud}^{\text{CKM}}|^2 f_\pi^2 m_N \sqrt{\lambda(m_{\mu N}^2, m_{\pi N}^2, m_N^2)} 
\times \left[ \frac{1 - m_{\mu N}^2}{m_N^2} - \frac{m_{\pi N}^2}{m_N^2} \left( 1 + \frac{m_{\pi N}^2}{m_N^2} \right) \right],
\]

where \(G_F\) is the Fermi constant, \(f_\pi\) is the pion decay constant, and \(V_{ud}^{\text{CKM}}\) is the Cabibbo-Kobayashi-Maskawa (CKM) matrix element involved.
The branching ratio of $D^0 \rightarrow P^- \mu^+ N$ is given by the expression [34]

$$\mathcal{B}(D^0 \rightarrow P^- \mu^+ N) = |U_{\mu N}|^2 \int dt \frac{d\mathcal{B}(D^0 \rightarrow P^- \mu^+ N)}{dt},$$

where

$$\frac{d\mathcal{B}(D^0 \rightarrow P^- \mu^+ N)}{dt} = \frac{G_F^2 \tau_{D^0}}{384 \pi^3 m_{D^0}^2 \hbar} |V_{c q}^{\text{CKM}}|^2 \left[\lambda(m_{\mu_D}^2, m_N^2, t)\lambda(m_{\mu_D}^2, m_N^2, t)\right]^{1/2} t^3$$

$$\times \left[\left[F_{0}^{DP}(t)\right]^2 C_+(t) + \left[F_0^{DP}(t)\right]^2 C_0(t)\right],$$

is the so-called differential canonical branching ratio [34], where $V_{c q}^{\text{CKM}}$ is the CKM matrix element (with $q = d, s$ for $P = \pi, K$); and $F_{0}^{DP}(t)$ and $F_{0}^{DP}(t)$ are the vector and scalar form factors for the $D \rightarrow P$ transition, respectively, which are evaluated at the square of the transferred momentum $t = (p_D - p_P)^2$. The kinematic coefficients $C_+(t)$ and $C_0(t)$ involved in Eq. (5) are defined as

$$C_+(t) = \lambda(m_{\mu_D}^2, m_N^2, t)[2t^2 + t(m_{\mu_D}^2 + m_N^2) + (m_{\mu_D}^2 - m_N^2)^2],$$

$$C_0(t) = 3(m_{\mu_D}^2 - m_N^2)[m_{\mu_D}^2(t + 2m_N^2 - m_N^2) + m_N^2(t - m_N^2)],$$

respectively, where $\lambda(x, y, z) = x^2 + y^2 + z^2 - 2(xy + xz + yz)$ is the usual kinematic Källen function. The total branching fraction is then obtained by integrating the differential canonical branching ratio over the full $t$ region $[(m_{\mu_D} + m_N)^2, (m_D - m_P)^2]$.

In later calculations we will use the following inputs [58]: $|V_{c d}^{\text{CKM}}| = 0.97417$, $|V_{c s}^{\text{CKM}}| = 0.218$, $|V_{c q}^{\text{CKM}}| = 0.997$, and $f_\pi = 130.2(1.7)$ MeV$^{-1}$. The masses of particles involved are taken from [58]. For the form factors associated with the $D \rightarrow P$ transition, we will use the theoretical predictions provided by the lattice QCD approach [61].

III. EXPERIMENTAL SENSITIVITY AT THE LHCb

The LHCb experiment is a perfect scenario to perform searches for LNV processes from heavy hadron decays, given the excellent detector performance and the large amount of data that has been collected, and that will be collected during future LHC runs [62–64]. Using an integrated luminosity of 2 fb$^{-1}$ collected from $pp$ collisions at a center-of-mass energy of 8 TeV, the LHCb collaboration observed the decays $D^0 \rightarrow \pi^+ \pi^- \mu^+ \mu^-$ and $D^0 \rightarrow K^+ K^- \mu^+ \mu^-$ [65]. These decays share the same type of particles in the final state as the LNV mode under study, and therefore we can use information from this analysis to extrapolate sensitivity considerations of $D^0 \rightarrow \text{LNV}$ in the framework of the LHCb experiment for different data sample sizes.

In the LHCb analysis the $D^0$ meson candidates, are extracted from a $D^{*+} \rightarrow D^0 \pi^+$ sample, produced directly from the $pp$ collision vertex. Given the small phase-space in this decay, there is a clean signature to select the $D^0$ candidates and reduce random background events. If the selected $D^0$ mesons were selected to come directly from the $pp$ collision, the sample of $D^0$ would have been larger, but the background level would have made unfeasible the extraction of the signal. The measured branching fraction for these decays are $\mathcal{B}_{\pi\pi} \equiv \mathcal{B}(D^0 \rightarrow \pi^+ \pi^- \mu^+ \mu^-) = (9.64 \pm 1.20) \times 10^{-7}$ and $\mathcal{B}_{KK} \equiv \mathcal{B}(D^0 \rightarrow K^+ K^- \mu^+ \mu^-) = (1.54 \pm 0.32) \times 10^{-7}$, where the quoted error contains the statistical and systematic uncertainties. The extracted signal yields, after combining several di-muon regions of study, are $N_{\pi\pi} = 561 \pm 28$ and $N_{KK} = 34 \pm 6$ signal events, as stated in Table 1 of Ref. [65], for $D^0 \rightarrow \pi^+ \pi^- \mu^+ \mu^-$ and $D^0 \rightarrow K^+ K^- \mu^+ \mu^-$ respectively. A conservative approximation is to consider that signal efficiency in the LHCb experiment will remain constant along the years, which is highly unlikely since the detector and algorithms are in constant improvement, thus the number of expected events of a decay with the same particles in the final state, should scale linearly with the luminosity and with the cross-section, which up to a good approximation scales linearly, as well, with the center-of-mass energy. Hence, a good estimation of the number of events of a decay with same final state as the LNV modes under study, for different conditions of luminosity $L$, $pp$ collisions at a different center-of-mass energy $\sqrt{s}$ and different branching fraction $B$, is

$$N_{S, hh}^{\text{LNV}}(L, \sqrt{s}, B) = \frac{L \cdot \sqrt{s} \cdot B \cdot N_{hh}}{2 \text{ fb}^{-1} \cdot 8 \text{ TeV} \cdot \mathcal{B}_{hh}},$$

where the subindex $hh$ refers to the different hadronic decays.

We have considered three different LHCb scenarios, $L=10, 50,$ and $300 \text{ fb}^{-1}$, which correspond to the typical projections of short, middle and long term expected integrated luminosities, respectively. Figure 2 shows an estimation of the number of events that can be detected in the LHCb experiment as a function of the branching fraction and integrated luminosity for the two modes. In Ref. [66] a study of the variation of the reconstruction efficiency, with fully simulated Monte Carlo samples dedicated to the LHCb experiment, is performed for long lived particles with mass within 20 - 80 GeV/c$^2$ and lifetimes in the range of 5 - 100 ps. Hence, the uncertainties shown in Fig. 2 correspond to the propagation of the error in the signal yields and in addition a 30% of uncertainty has been assigned to account for efficiency effects in the reconstruction of massive lived neutrinos. In Table I the number of expected LNV events in LHCb, for a given

1 See the review “Leptonic decays of charged pseudoscalar mesons” from PDG [58].
value of integrated luminosity and branching fraction is reported, showing that in long term, for values of branching fraction above $10^{-10}$ there will be chances to detect LNV $D^0 \rightarrow h^- h^+ \mu^+ \mu^+$ decays.

![Graph showing number of expected events at LHCb](image)

**FIG. 2.** Number of expected events at LHCb, for $D^0 \rightarrow \pi^- \pi^+ \mu^+ \mu^+$ (top) and $D^0 \rightarrow K^- K^+ \mu^+ \mu^+$ (bottom) as a function of the branching fraction, for different luminosity values: $\mathcal{L} = 10$ fb$^{-1}$ (solid green), 50 fb$^{-1}$ (dotted blue), and 300 fb$^{-1}$ (dashed red). The filled region represents the uncertainty in the computation.

However, the number of detected events is not always a good indicator of the sensitivity to claim discovery of such type of events. In this case, the signal significance will give a better estimation of the real chance of observing the LNV $D^0$ decay. In a large-sample limit, the discovery significance $Z$, is given by [58]

$$Z = \sqrt{2 \left( (N_S + N_B) \log \frac{N_S + N_B}{N_B} - N_S \right)} \quad (9)$$

where $N_S$ and $N_B$ denote the number of signal and background events respectively. In Table 1 of Ref [65], not only number of signal events are quoted but also the significance, therefore a background estimation can be done by finding the roots of Eq. 9, and after we can extrapolate to our specific energy and luminosity scenario. In the LHCb analysis two main sources of background are treated, random combinatoric and peaking background from misidentified hadrons as muons. Same sources background will be present in the LNV modes and therefore we do not split among those background sources, and instead consider all sources as one. From performing the procedure above mentioned, we found in the $D^0 \rightarrow \pi^+ \pi^- \mu^+ \mu^-$ LHCb sample a about 235 ± 15 background events, and for the $D^0 \rightarrow K^- K^+ \mu^+ \mu^-$ a total of 7 ± 3. Where in both cases the uncertainty is assigned as $\sqrt{N_B}$. Assuming that the background scales with the luminosity and with the center-of-mass energy, just as the signal yield, the extrapolation of background events expected in the LNC decay modes is computed as

$$N_{B, hh}^{LNV}(\mathcal{L}, \sqrt{s}) = \frac{L \cdot \sqrt{s} \cdot N_{B, hh}}{2 \text{ fb}^{-1} \cdot 8 \text{ TeV}} \quad (10)$$

Figure 3 shows how the signal significance changes with the branching fraction of the LNV decays. The extrapolated background level is quoted in Table II, where it is also quoted the minimum branching fraction of the LNV from which observation can be achieved in the LHCb experiment. This show that for a long term expected integrated luminosity of 300 fb$^{-1}$, branching fractions of the order $\mathcal{O}(10^{-8})$ would be reachable, allowing to improve by several orders of magnitude the experimental limits obtained by E791 experiment.

**TABLE I.** Number of expected LNV events for a given value of integrated luminosity and branching fraction.

| $\mathcal{L}$ (fb$^{-1}$) | $B$ | $N_{S, \pi\pi}^{LNV}$ | $N_{S, KK}^{LNV}$ |
|--------------------------|-----|----------------------|-------------------|
| $10^{-7}$                | 509 ± 167 | 193 ± 78 |
| $10^{-8}$                | 51 ± 17 | 19 ± 8 |
| $10^{-9}$                | 5 ± 2 | 2 ± 1 |
| $50$                     | 2546 ± 836 | 966 ± 392 |
| $10^{-8}$                | 255 ± 84 | 97 ± 39 |
| $10^{-9}$                | 26 ± 8 | 10 ± 4 |
| $10^{-10}$               | 3 ± 1 | - |
| $300$                    | 15276 ± 5016 | 5795 ± 2350 |
| $10^{-8}$                | 1528 ± 502 | 580 ± 235 |
| $10^{-9}$                | 153 ± 50 | 58 ± 23 |
| $10^{-10}$               | 15 ± 5 | 6 ± 2 |

**IV. EXCLUSION REGIONS ON THE PARAMETER SPACE ($m_N, |V_{\mu N}|^2$)**

Based on the LHCb sensitivity analysis presented in the previous Sec. III, in the following, we examine the bounds on the parameter space of a heavy sterile neutrino
LNV signal significance in LHCb

FIG. 3. Signal significance expected in the LHCb experiment, for \(D^0 \rightarrow \pi^- \pi^- \mu^+ \mu^+\) (top) and \(D^0 \rightarrow K^- K^- \mu^+ \mu^+\) (bottom) as a function of the branching fraction, for different luminosity values: \(L = 10 \text{ fb}^{-1}\) (solid green), \(50 \text{ fb}^{-1}\) (dotted blue), and \(300 \text{ fb}^{-1}\) (dashed red). The filled region represents the uncertainty in the computation. Horizontal black dot-dashed lines correspond to 3\(\sigma\) and 5\(\sigma\) limit.

TABLE II. Extrapolated background level, and branching fraction from which there can be observation of LNV modes at LHCb

\[
\begin{array}{cccc}
L (\text{fb}^{-1}) & B_{\text{LNV}}^{\pi \pi \mu \mu} & B_{\text{LNV}}^{\pi \pi \mu \mu} & B_{\text{LNV}}^{KK} \\
10 & 2056 & > 3.4 \times 10^{-8} & 61 & > 1.5 \times 10^{-8} \\
50 & 10281 & > 1.5 \times 10^{-8} & 306 & > 6.6 \times 10^{-9} \\
300 & 61687 & > 6.1 \times 10^{-9} & 1837 & > 2.7 \times 10^{-9} \\
\end{array}
\]

\(m_N, |V_{\mu N}|^2\) that can be achieved from the experimental searches on \(D^0 \rightarrow (\pi^- \pi^-, K^- \pi^-) \mu^+ \mu^+\) at the LHCb experiment.

To constraint the squared magnitude \(|V_{\mu N}|^2\) as a function of the mass \(m_N\), the following relation obtained from Eq. (1) can be used for that purpose

\[
|V_{\mu N}|^2 = \left( \frac{B(D^0 \rightarrow P^- \pi^- \mu^+ \mu^+ \, h)}{B(D^0 \rightarrow P^- \mu^+ N) \times \Gamma(N \rightarrow \mu^+ \pi^-) / \gamma} \right)^{1/2},
\]

where \(B(D^0 \rightarrow P^- \mu^+ N)\) and \(\Gamma(N \rightarrow \mu^+ \pi^-)\) are given by Eqs. (5) and (3), respectively. We will consider heavy neutrino lifetimes of \(\tau_N = [5, 100] \text{ ps}\) as benchmark points in our analysis. This will allow us to extract limits on \(|V_{\mu N}|^2\) without any additional assumption on the relative size of the mixing matrix elements.

Considering an expected LHCb sensitivity on the branching fractions of the order \(B(D^0 \rightarrow P^- \pi^- \mu^+ \mu^+ < 10^{-9}\) for \(300 \text{ fb}^{-1}\), in Figs. 4(a) and 4(b) we show the exclusions regions on the \((m_N, |V_{\mu N}|^2)\) plane obtained from future searches on \(D^0 \rightarrow \pi^- \pi^- \mu^+ \mu^+\) and \(D^0 \rightarrow K^- \pi^- \mu^+ \mu^+\), respectively. In both cases, the black, blue, and gray regions represent the bounds obtained for heavy neutrino lifetimes of \(\tau_N = 5\) and \(100\) \text{ ps}, respectively. We also plot the exclusion limits obtained from searches on \(|\Delta L| = 2\) channels, \(K^- \rightarrow \pi^+ \mu^- \mu^-\) from NA48/2 (taken for \(\tau_N = 1000\) \text{ ps}\) [48] and \(B^- \rightarrow \pi^+ \mu^- \mu^-\) from LHCb [54], for comparison. For the \(B^- \rightarrow \pi^+ \mu^- \mu^-\) channel, we compare with the revised limit [32] from the LHCb analysis [54]. In the range of \(m_N\) relevant for \(D^0 \rightarrow (\pi^- \pi^-, K^- \pi^-) \mu^+ \mu^+\) channels, we can observe that the most stringent bound is given by \(K^- \rightarrow \pi^+ \mu^- \mu^-\), which can reach \(|V_{\mu N}|^2 \sim \mathcal{O}(10^{-5})\), but only for a very narrow mass window of \([0.25, 0.38]\) GeV. For \(m_N > 0.38\) GeV, the four-body channels under study would improve the region of \(|V_{\mu N}|^2\) covered by the channel \(B^- \rightarrow \pi^+ \mu^- \mu^-\).

For further comparison, in Figs. 4(a) and 4(b) we also show the limits coming from different search strategies such as Belle [72], DELPHI [73], NA3 [74], and CHARMII [75] experiments\(^2\). As can be seen, our \(|\Delta L| = 2\) channels proposals have comparable sensitivity that different search strategies in the region mass where these overlap. In particular, searches on \(D^0 \rightarrow K^- \pi^- \mu^+ \mu^+\) could slightly improve those limits in the mass window of \(\sim [0.38, 1]\) GeV.

We encourage the experimental colleagues from the LHCb experiment to look for heavy Majorana neutrinos through the search on four-body \(|\Delta L| = 2\) decays of the \(D^0\) meson, thus complementing previous LHCb analysis [52–54]. Additionally, these searches can be also performed at the Belle II and BESIII experiments.

\(^2\) For recent reviews on the theoretical and experimental status of different GeV-scale heavy neutrino search strategies see for instance Refs. [67–71] and references therein.
FIG. 4. Exclusion regions on the \((m_N, |V_{\mu N}|^2)\) plane for (a) \(\text{BR}(D^0 \rightarrow \pi^- \mu^- \mu^+ \mu^+) < 10^{-9}\) and (b) \(\text{BR}(D^0 \rightarrow K^+ \pi^- \mu^- \mu^+) < 10^{-9}\) at LHCb. The black, blue, and gray regions represent the bounds obtained for heavy neutrino lifetimes of \(\tau_N = 5\) and 100 ps, respectively. Limits provided by \(K^- \rightarrow \pi^- \mu^- \mu^-\) [48], \(B^- \rightarrow \pi^- \mu^- \mu^-\) [32], Belle [72], DELPHI [73], NA3 [74], and CHARMII [75], are also included for comparison.

V. CONCLUSIONS

We have explored a charmed search to track the possible signals of lepton-number-violation at the LHCb experiment, due to the copious charm production. We studied the four-body \(\Delta L = 2\) decays of the \(D^0\) meson, \(D^0 \rightarrow P^- \mu^- \mu^+ \mu^+\) \((P = \pi, K)\), induced by an on-shell Majorana neutrino \(N\) with a mass of few GeV. We performed an exploratory study on the potential sensitivity (signal significance) that LHCb experiment could achieve for these \(\Delta L = 2\) processes. For a long term expected integrated luminosity of 300 fb\(^{-1}\), we found that branching fractions of the order \(\mathcal{O}(10^{-9})\) might be feasible. Such a sensitivity will improve by several orders of magnitude the experimental limits obtained by E791. It is also found that for a neutrino mass window of \(0.25 \leq m_N \leq 1.62\) GeV, exclusion regions on the parameter space \((m_N, |V_{\mu N}|^2)\) that could be obtained from their experimental search will have comparable sensitivity that previous bounds. Particularly, searches on \(D^0 \rightarrow K^+ \pi^- \mu^- \mu^+\) could slightly improve bounds in the range of \(\sim [0.38, 1]\) GeV.
