Reconstructing the structural connectivity between interacting units from observed activity is a challenge across many different disciplines. The fundamental first step is to establish whether or to what extent the interactions between the units can be considered pairwise and, thus, can be modeled as an interaction network with simple links corresponding to pairwise interactions. In principle this can be determined by comparing the maximum entropy given the bivariate probability distributions to the true joint entropy. In many practical cases this is not an option since the bivariate distributions needed may not be reliably estimated, or the optimization is too computationally expensive. Here we present an approach that allows one to use mutual informations as a proxy for the bivariate distributions. This has the advantage of being less computationally expensive and easier to estimate. We achieve this by introducing a novel entropy maximization scheme that is based on conditioning on entropies and mutual informations. This renders our approach typically superior to other methods based on linear approximations. The advantages of the proposed method are documented using oscillator networks and a resting-state human brain network as generic relevant examples.

Pairwise measures of dependence such as cross-correlations (as measured by the Pearson correlation coefficient or covariance matrix) and mutual information are widely used to characterize the interactions within complex systems. They are a key ingredient to techniques such as principal component analysis, empirical orthogonal functions, and functional networks [1–3]. These techniques are widespread since they provide greatly simplified descriptions of complex systems, and allow for the analysis of what might otherwise be intractable problems [4]. In this paper we study how faithfully these measures alone can represent a given system. With the increasing use of functional networks this topic has received much attention recently, and many technical concerns have been brought to light dealing with the inference of these networks. Previous studies have shown that the estimates of the functional networks can be negatively affected by properties of the time series [5–7], as well as properties of the measure of association, e.g. cross-correlations [8–11]. In this work however, we address a more fundamental question: How well do pairwise measurements represent a system?

In principle this can be evaluated using the framework laid out in [12] as later applied in [13], where they assessed the rationale of only looking at the pairwise relationships between neurons. They examined how well the maximum entropy distribution, consistent with all the pairwise probability distributions, described the system. If the system is not well described by this maximum entropy distribution then we know from the work of Jaynes [14] that other information beyond pairwise relationships would need to be taken into account. Similar analyses have since been applied in neuroscience [15–17], as well as in genetics [18], linguistics [19], economics [20], and to the supreme court of the United States [21].

However, the data to accurately estimate the needed bivariate probability distributions may not be available. To get around this some researchers have used the first two moments of the variables as constraints instead of the full bivariate distributions [22, 23] — effectively using the cross-correlations as their constraints. In the case of binary variables, as in the original work [13], this is equivalent to conditioning on the bivariate distributions. For larger cardinality variables this is only an approximation though, as the cross-correlation is only sensitive to linear relationships [24]. Systems where larger cardinalities and nonlinear behaviour are thought to play a significant role such as in coupled oscillators — which have been used to model systems as diverse as pacemaker cells and crickets [25] — are, however, rather the norm than an exception [24]. In particular, we show here that this plays a significant role in a resting-state human brain network.

In order to retain the attractive properties of the cross-correlation and simultaneously capture a much wider range of relationships we propose using the mutual information. Mutual information can detect arbitrary pairwise relationships between variables, and is only non-zero when the variables are pairwise independent, making it the ideal measure [26]. However, while calculating the maximum entropy given the moments of a distribution results in simple equations in the probabilities, using mutual informations as constraints results in transcendental equations which are much harder to solve. We circumvent this problem here using the set theoretic formulation of
information theory [27], which gives us an upper bound on the maximum entropy that is saturated in many cases.

The set theoretic formulation of information theory allows us to map information theoretic quantities to the regions of an information diagram, a variation of a Venn diagram. The information diagram for three variables is shown in Fig. [1] with the associated information theoretic quantities labeled [47]: entropy, \( H(X) = \sum p(x) \log(p(x)) \); conditional entropy, \( H(X|Y,Z) = \sum p(x,y,z) \log(p(x|y,z)) \); mutual information, \( I(X,Y) = \sum p(x,y) \log\left(\frac{p(x,y)}{p(x)p(y)}\right) \); conditional mutual information, \( I(X;Y|Z) = \sum p(x,y,z) \log\left(\frac{p(x|y,z)}{p(x)p(y|z)}\right) \); and multivariate mutual information, \( I(X;Y;Z) = I(X;Y) - I(X;Y|Z) \).

![Diagram showing information quantities](image)

**FIG. 1:** (Color online) The information diagram for 3 variables. It contains 7 regions corresponding to the possible combinations of 3 variables, with their corresponding information theoretic quantities defined in the text. The univariate entropy \( H(X) \) is the sum of all the regions in the red circle, and the mutual information \( I(Y;Z) \) is the sum of all the regions in the blue oval.

We illustrate our method using systems of coupled oscillators, as they commonly occur in nature and are used to model a large variety of systems [23]. In particular we look at the Kuramoto model [28, 29] as a paradigmatic example that is capable of a wide range of dynamics from synchronization to chaos [30], and hence provides an excellent test bed for our method.

**Method:** Given a set of \( N \) variables \( \{X\}_N \), we want to know how well the cross-correlation or mutual information between all pairs of variables can encode the state of the system. To do this we first determine the maximum entropy consistent with the given measure of similarity, \( H_m(\{X\}_N) \). This means that any model of the system consistent with the \( \binom{N}{2} \) values of the similarity measure can have an entropy of at most \( H_m(\{X\}_N) \). From the work of Jaynes [14], we also know that any model of the system with a smaller entropy must implicitly or explicitly include information beyond these values. As a result the true joint entropy, \( H(\{X\}_N) \), will always be less than or equal to \( H_m(\{X\}_N) \).

As the next step, we consider the information gained by using a given measure compared to the information gained by knowing the full joint probability distribution as opposed to the univariate distributions. The latter information gain is given by the multi-information (also called total correlation [31]), \( I_N(\{X\}_N) = H_I(\{X\}_N) - H(\{X\}_N) \geq 0 \), where \( H_I(\{X\}_N) = \sum_i H(X_i) \) is the entropy if all variables were independent. We similarly define the measure information \( I^m_N(\{X\}_N) = H_I(\{X\}_N) - H_m(\{X\}_N) \), to be the shared information between a set of variables given a measure. The fraction of information retained by describing the system with a given measure is then \( 0 \leq I^m/I_N \leq 1 \).

When using the cross-correlation, estimating \( H_m \) is straightforward. Estimates of the first two moments of the variables uniquely determine the cross-correlations, and can be used as constraints in a Lagrange multiplier problem solving for \( H_m \). The resulting probability distribution \( P_m(\{X\}_N) \) is the Boltzmann distribution \( P_m(\{X\}_N) = \exp\left(\sum_i h_i x_i + \sum_{i>j} J_{ij} x_i x_j\right) \), where \( h_i \) and \( J_{ij} \) are the Lagrange multipliers [33].

When using mutual information, estimating \( H_m \) with Lagrange multipliers is much harder as the derivatives of the Lagrange function are transcendental functions in \( P_m(\{X\}_N) \). Instead, we use the mutual informations and univariate entropies as constraints, and draw on the structure of information diagrams. Each univariate entropy and mutual information corresponds to a region in the information diagram that can be written as a sum of a number of atomic regions (atoms). Thus, as seen in Fig. [1] we obtain constraints of the form:

\[
\text{const} = I(Y;Z) = I(Y;Z|X) + I(X;Y;Z),
\]

\[
\text{const} = H(X) = H(X|Y,Z) + I(X;Y|Z)
\]

In general, a system of \( N \) variables results in \( \binom{N}{1} \) univariate entropy constraints, \( \binom{N}{2} \) mutual information constraints, and \( A = \sum_{k=1}^{N} \binom{N}{k} = 2^N - 1 \) atoms to be determined. In the simplest case of \( N = 3 \) variables we have six constraints and \( A = 7 \) regions to specify, see Fig. [1]. This means we only have one free parameter, making the maximization process particularly easy in this case; in general there are \( \sum_{k=3}^{N} \binom{N}{k} \) free parameters.

Apart from the chosen constraints defined above, there are also general constraints on the values of the sub-regions ensuring they define a valid information diagram, i.e. that there exists a probability distribution with corresponding information-theoretic quantities. A family of such constraints (so-called Shannon inequalities) can be inferred from the fundamental requirement that, for discrete variables, (conditional) entropies and mutual informations are necessarily non-negative: A) \( H(X_i|\{X\}_N - X_i) \geq 0 \); B) \( I(X_i,X_j|\{X\}_N - \{X_i,X_j\}) \geq 0 \), where \( i \neq j \) and \( \{X\}_N - \{X_i,X_j\} \) [13]. Each inequality can also be represented as a sum of atomic regions, e.g.

\[
I(X_1;x_2|x_3) = I(X_1;x_2|x_3,x_4) + I(X_1;x_2;x_4|x_3) \geq 0.
\]
Not so-well known, for $N \geq 4$, there are also inequalities that are not deducible from the Shannon inequalities, so called non-Shannon inequalities [27]. In principle, these inequalities may be included in our maximization problem; however, they have not yet been fully described. Therefore, we suggest constructing the diagram with the maximum entropy that satisfies the problem specific constraints and is consistent with the Shannon inequalities. As it may violate the non-Shannon inequalities, it may not represent a valid distribution. However, the sum of the atomic regions would still be an upper bound on the entropy $H_m$, and thus provide a lower bound on $I^m/I_N$. Notably, for the particular (and in our simulations common) case where all $A$ elements are non-negative — which is always true for $N = 3$ — one can prove that the bound is attainable [32].

To summarize, the task of finding the maximum entropy conditioned on the univariate entropies, mutual informations, and elemental Shannon inequalities, can be solved using linear optimization: Each constraint will take the form of a linear (in-)equality, as in Eqs. (1), (3), be solved using linear optimization: Each constraint will take the form of a linear (in-)equality, as in Eqs. (1), (3), and we maximize the N-variate entropy by maximizing the sum over all $A$ atoms of the information diagram.

Example of an Nonlinear Pairwise Distribution: We now give an example illustrating how the mutual information can better detect pairwise relationships then the cross-correlation. Consider a set of variables $\{X\}_{N}$: each variable is drawn uniformly from the set $\{-1,0,1\}$, and all variables are simultaneously 0 or independently distributed among $\{-1,1\}$. The cross-correlation between any pair of variables is zero, and therefore consistent with the hypothesis that all variables are independent. Therefore, the fraction of information captured by the cross-correlation is $I^m/I_N = 0$. However, there is a significant amount of mutual information between the variables.

Since $P(X_i|X_j) = P(X_i,X_j)$ for all $i$ and $j$, all the conditional mutual informations are zero. Therefore, the only nonzero atoms in the information diagram will be the N-variate mutual information $I(X_1;...,X_N) = I(X_1;X_2)$, and the conditional entropies $H(X_i|X_{\{X\}_{N}} = X_i) = 2/3$ bits. This is the maximum entropy diagram consistent with the pairwise mutual informations and univariate entropies, so the expected result using the mutual information is $I^m/I_N = 1$. We can see why this is the case by starting with the information diagram for 2 variables (which is fixed from our conditions), and successively adding new variables. The addition of each new variable adds $2/3$ bits to the total entropy — which is the maximal amount consistent with the mutual informations.

**Kuramoto Model:** The Kuramoto model is a dynamical system of $N$ phase oscillators with all to all coupling proportional to $K$ [25, 29]. The $i$th oscillator has an intrinsic frequency of $\omega_i$, a phase of $\theta_i$, and its dynamics is given by $\frac{d\theta_i}{dt} = \omega_i + K \sum_{j=1}^{N} \sin(\theta_j - \theta_i) + \eta_i(t)$. Here, we have followed [33] and added a dynamical noise term to mimic natural fluctuations and environmental effects; $\eta_i(t)$ is drawn from a Gaussian distribution with correlation function $\langle \eta_i(t)\eta_j(t') \rangle = G\delta_{ij} \delta(t - t')$, where $G$ determines the amplitude of the noise.

For values of $K$ above a critical threshold, $K > K_c$, synchronization occurs [25]. In the limit of constant phase differences the dynamics are trivial, and knowledge of one oscillator will specify the phase of all others. Therefore, pairwise information is sufficient to describe the system in this case. Yet, the presence of noise results in random perturbations of the phases and typically prevents constant phase differences [33] such that only $I^m/I_N \lesssim 1$ is expected. In the weak coupling regime when synchronization is absent, it is nontrivial what $I^m/I_N$ should be.

To estimate $I^m/I_N$ and to establish the importance of the level of discretization or cardinality, we first discretize the phase of each oscillator into $n$ states. The region from zero to $2\pi$ is divided into $n$ intervals, such that the oscillator is equally likely to be found in each one, and all values of $\theta$ are mapped to the average value of the points in their interval. Discretizing the system using $n$ equally sized intervals, each having a length $2\pi/n$, did not noticeably alter our results.

To provide clear proofs of principle, we focus on three-oscillator systems in the following as this is the smallest system size at which the results are non-trivial. Similar results hold for larger systems and when only a subset of oscillators is observed as shown in the Supplementary material [31]. Specifically, we consider three different cases: (i) all oscillators have the same intrinsic frequency, (ii) all oscillators have unique intrinsic frequencies and are still synchronized, and (iii) all oscillators have unique intrinsic frequencies and the entire system and all subsystems are unsynchronized (“weak coupling regime”). For three-oscillator systems, the corresponding parameter regimes in the absence of noise have been carefully documented in Ref. [30].

For each of the three cases examined we created ensembles of 100 three-oscillator systems, where each element of the ensemble will have randomly sampled frequencies [19]. These ensembles are studied in two different noise regimes; $G = 0.001$ and $G = 0.5$. The same ensemble of frequencies is used in both noise regimes.

In the first case all oscillators are synchronized with $\omega_1 = \omega_2 = \omega_3$, and $K = 1.65$. Recall, in the synchronized case we expect $E[I^m/I_N] \approx 1$. This is indeed what we see in the low noise case, $G = 0.001$, Fig. 2 A; though the mutual information preserves slightly more information at larger cardinalities. However, for increased noise, $G = 0.5$, the cross-correlation performs poorly at larger cardinalities, while the mutual information behaves robustly, Fig. 2 D.

For the second case, where the oscillators are synchronized with different intrinsic frequencies, we use $\Delta_1/\Delta_2 = 1.11$, $K/\Delta_2 = 4$, and $K = 2.20$, where
The multi-information, with \(|\hat{m}| > 2\), encodes virtually no information about the system for situations, we apply it to neuroimaging data, in a similar context as in [15]. In particular, we want to assess to what extent the multivariate activity distribution is determined by purely bivariate dependence patterns. The used data consist of time series of functional magnetic resonance imaging signal from 96 healthy volunteers measured using a 3T Siemens Magnetom Trio scanner in IKEM (Institute for Clinical and Experimental Medicine) in Prague, Czech Republic. Average signals from 12 regions of the fronto-parietal network were extracted using a brain atlas [35]. After preprocessing and denoising as in [39], the data were temporally concatenated. Each variable was further discretized to 2 or 3 states using equiquantal binning. Using our approach, we find \(I^m/I_N = 0.77\) for both the 2-state and 3-state discretizations, suggesting that bivariate dependence patterns capture the dominant proportion of the information. For 2-state discretization, this is smaller then in [15]. However, for the 3-state discretization it provides a much higher estimate of the bivariate dependence role than the method taking into account only correlations, as in the case of the Kuramoto model. This suggests that only when accounting also for non-linear coupling, the bivariate dependences provide sufficient data structure approximation resolving the apparent inconsistency of the results in [15]. This is also true for other brain networks [32].

Discussion: Our method allows for potential speedups over the maximum entropy calculation when conditioning on the bivariate distributions, as well as when conditioning on the cross-correlations. In both of these cases solving the associated Lagrange multiplier equations are non-linear optimization problems. The maximum entropy distribution could also be found using iterative fitting routines like [37], but in these cases the problem will still scale like \(n^N\) (\(n\) is the cardinality of the variables). While there are pathological linear optimization problems that scale exponentially with \(N\), there will always be a slightly perturbed problem such that our method will scale polynomially [38].

Researchers have so far relied on conditioning on the cross-correlations when insufficient data is available to estimate the bivariate distributions. They either coarse grain to binary variables where it is equivalent to conditioning on the distributions [15] — potentially loosing important information — or use higher cardinality variables where it is only a linear approximation [22,23]. Our approach based on mutual information can be applied in these cases; the associated entropies can be estimated with as few as \(2^{H/2}\) data points [39] (\(H\) is measured in bits). While this maximization has previously been prohibitively difficult, our work shows that it is feasible allowing it to become widely applicable and serve as a starting point before considering multivariate information measures [40,41]. Additionally, if our method returns a small \(I^m/I_N\) this suggests both that the faithfulness assumption used in causal inference is violated [42–45], and that there is synergy among the variables [46].

Our calculation of \(H_m\) for the mutual information is free of distributional assumptions, computing the maximum entropy in the general space of arbitrary cardinality variables. This may result in higher entropy estimates than methods that consider predefined cardinality, e.g., binary variables. Notably, our simulations suggest that estimating \(H_m\) in this way provides comparable, or substantially lower, entropy estimates than \(H_m\) for the cross-correlation, which explicitly constrains the cardinality. This makes the technique competitive even when a specific cardinality could be reasonably assumed.
Conclusions: In this work we introduced a novel method to determine the importance of pairwise relationships by estimating the maximum entropy conditioned on the mutual informations. We showed that by mapping this problem to a linear optimization problem it could also be efficiently computed. Using the generic case of coupled oscillators we gave a proof of principle example where our method was able to widely outperform conditioning on the cross-correlations. The example of the resting-state brain network showed that this also carries over to real world applications, highlighting the potential of the method when cardinalities larger than two and nonlinear behavior are important.

This project was financially supported by NSERC (EM and JD) and by the Czech Science Foundation project No. 13-23940S and the Czech Health Research Council project NV15-29835A (JH). All authors would like to thank the MPIPKS for its hospitality and hosting the international seminar program “Causality, Information Transfer and Dynamical Networks”, which stimulated some of the involved research. We also would like to thank P. Grassberger for many helpful discussions.

Supplementary Material

We simulated a system of 100 Kuramoto oscillators, as described in our manuscript, in two regimes: i) All oscillators are synchronized, $K = 4$; ii) the oscillators are partially synchronized with more than 20 different synchronized clusters, $K = 1.75$. In both cases we use the same set of intrinsic frequencies (drawn from a normal distribution with mean zero and unit variance), and a noise level $G = 0.001$.

Similar to the analysis done in Ref. [13], we analyzed the effects of sampling from a larger system by randomly selecting $T$ of the 100 oscillators and calculating $I^m/I_T$ for those oscillators. For each tuple size, $T$, we repeated this one hundred times, using the same sets of tuples in both regimes, and computed $\hat{E}[I^m/I_T]$ as the average of these values. As in our previous examples, our method outperforms the cross-correlation in the synchronized case (see Fig. 3), as well as for weaker coupling (see Fig. 4). Our method results in $\hat{E}[I^m/I_T] \lesssim 1$ in both regimes, and across all discretizations and tuple sizes, while the cross-correlation only does so for binary variables.
