A broadband technique for robust adiabatic rotation and conversion of light polarization is proposed. It uses the analogy between the equation describing the polarization state of light propagating through an optically anisotropic medium and the Schrödinger equation describing coherent laser excitation of a three-state atom. The proposed technique is analogous to the stimulated Raman adiabatic passage (STIRAP) technique in quantum optics; it is applicable to a wide range of frequencies and it is robust to variations in the propagation length and the rotary power.

I. INTRODUCTION

A simple way to describe the polarization state of light, which has been known for many years in optics, is by the Stokes vector, which is depicted as a point on the so-called Poincaré sphere [1, 2]. The Stokes vector, for instance, is a particularly convenient tool to describe the change of the polarization state of light transmitted through anisotropic optical media [2–4].

The equation of motion for the Stokes vector in a medium with zero polarization dependent loss (PDL) has a torque form [2–4]. This fact has been used recently to draw analogies between the motion of the Stokes vector and a spin-1/2 particle in nuclear magnetic resonance and an optically driven two-state atom in quantum optics, both described by the Schrödinger equation [6–8].

Here we propose a technique for controlled robust conversion of the polarization of light transmitted through optically anisotropic media with no PDL. The technique is analogous to stimulated Raman adiabatic passage (STIRAP) in quantum optics [13–15] and hence enjoys the same advantages as STIRAP in terms of efficiency and robustness.

For any traditional polarization devices the rotary power (the phase delay between the fast and slow eigen-polarizations) scales in proportion to the frequency of the light and thus such devices are frequency dependent: a half-wave plate is working for exactly one single frequency. On the contrary, the adiabatic polarization conversion proposed here is frequency independent: any input polarization will be transformed to the same output polarization state regardless of the wavelength. It acts intrinsically as a broadband device limited only by the absorptive characteristics of the device instead of its birefringence bandwidth. Moreover, the proposed technique is robust against variations in the length of the device, in the same fashion as quantum-optical STIRAP is robust against variations in the pulse duration.

II. STOKES POLARIZATION VECTOR

We first consider a plane electromagnetic wave traveling through a dielectric medium in the z direction. The medium is anisotropic and with no PDL, therefore the polarization evolution is given with the following torque equation for the Stokes vector [2, 4, 6–9, 11, 12]:

\[
\frac{d}{dz}S(z) = \Omega(z) \times S(z),
\]

where \(z\) is the distance along the propagation direction, and \(S(z) = [S_1(z), S_2(z), S_3(z)]\) is the Stokes polarization vector shown in Fig. 1. Every Stokes polarization vector corresponds to a point on the Poincaré sphere and vice versa. The right circular polarization is represented by the north pole, the left circular polarization by the south pole, the linear polarizations by points in the equatorial plane, and the elliptical polarization by the points between the poles and the equatorial plane. \(\Omega(z) = [\Omega_1(z), \Omega_2(z), \Omega_3(z)]\) is the birefringence vector of the medium: the direction of \(\Omega(z)\) is given by the slow eigenpolarization and its length \(|\Omega(z)|\) corresponds to the rotary power.

III. SCHRÖDINGER EQUATION FOR A THREE-STATE QUANTUM SYSTEM

When one of the components of the vector \(\Omega(z)\) is zero, then Eq. (1) is mathematically equivalent to the Schrödinger equation for a coherently driven three-state quantum A system on exact resonances with the carrier frequencies of the external fields. This is readily seen by examining the time-dependent Schrödinger equation, which in the rotating-wave approximation (RWA) reads

\[
\frac{i\hbar}{dt}c(t) = H(t) c(t).
\]

Here \(c(t)\) is a column vector of the probability amplitudes \(c_n(t) (n = 1, 2, 3)\) of the three states \(\psi_1, \psi_2\) and \(\psi_3\), and
The quantum evolution associated with the Λ system is characterized by the Hamiltonian matrix \[ H(t) = \frac{\hbar}{2} \begin{pmatrix} 0 & \Omega_1(t) & 0 \\ \Omega_1(t) & 0 & \Omega_2(t) \\ 0 & \Omega_2(t) & 0 \end{pmatrix} \] (3)

We have here assumed both two-photon and single-photon resonances. The two slowly varying Rabi frequencies \( \Omega_1(t) \) and \( \Omega_2(t) \) parameterize the strengths of each of the two fields; they are proportional to the dipole transition moments \( d_{ij} \) and to the electric-field amplitudes \( E_k(t) \): \( \Omega_1(t) = -d_{12} \cdot E_1(t) \) and \( \Omega_2(t) = -d_{23} \cdot E_2(t) \); hence each of them varies as the square root of the corresponding intensity.

The quantum evolution associated with the Λ system is easily understood with the use of adiabatic states, i.e. the three instantaneous eigenstates \( \varphi_k(t) \) of the RWA Hamiltonian (3). The adiabatic state \( \varphi_0(t) \) corresponding to a zero eigenvalue is particularly noteworthy, because it has no component of state \( \varphi_3 \),

\[ \varphi_0(t) = \frac{\Omega_3(t)}{\sqrt{\Omega_1^2(t) + \Omega_2^2(t)}} \psi_1 - \frac{\Omega_1(t)}{\sqrt{\Omega_1^2(t) + \Omega_2^2(t)}} \psi_3. \] (4)

This state therefore does not lead to fluorescence and is known as a dark state [13, 15]. If the motion is adiabatic [13, 15], and if the state vector \( \Psi(t) \) is initially aligned with the adiabatic state \( \varphi_0(t) \), then the state vector remains aligned with \( \varphi_0(t) \) throughout the evolution. This occurs if the pulses are ordered counterintuitively, \( \Omega_2(t) \) before \( \Omega_1(t) \): then the composition of the dark state \( \varphi(t) \) will progress from initial alignment with \( \psi_3 \) to final alignment with \( \psi_1 \). Hence in the adiabatic regime the complete population will be transferred adiabatically from state \( \psi_1 \) to state \( \psi_3 \). This important feature of complete transfer under full control has made STIRAP a widespread preparation technique for experiments relying on precise state control [14, 15]. The formalism can be applied to other systems, including classical ones [16, 15], by making use of the similarity of the respective equations to Eqs. (2) and (4).

**IV. ADIABATIC CONVERSION OF LIGHT POLARIZATION**

Returning to light polarization, two special cases are particularly interesting.

**Case A**: \( \Omega_0(z) = 0 \). With the redefinition of variables \( S_1(t) = -i c_3(t), \quad S_2(t) = i c_1(t), \quad S_3(t) = -c_2(t) \), the Schrödinger equation (2) turns into the form (4), if we map the time dependence into the coordinate dependence. By using this analogy we can write down a superposition \( \sigma(z) \) of the polarization components \( S_1(z) \) and \( S_2(z) \) of the Stokes vector, which corresponds to the dark state \( \varphi_0(t) \), Eq. (4):

\[ \sigma(z) = \frac{\Omega_1(z) S_1(z) + \Omega_2(z) S_2(z)}{|\Omega(z)|}. \] (5)

When \( \Omega_1(z) \) precedes \( \Omega_2(z) \) the polarization superposition (5) has the following asymptotic values

\[ S_1(z_i) \xrightarrow{\psi_1 \rightarrow \psi_2} S_2(z_f). \] (6)
Thus if initially the light is linearly polarized in horizontal direction, \( S(z_f) = (1, 0, 0) \), we end up with a linearly polarized light rotated by \( 45^\circ \), \( S(z_f) = (0, 1, 0) \) (see Fig. 1 (a)). The process is reversible; hence if we start with a linear polarization rotated by \( 45^\circ \) and apply a reverse field order (\( \Omega_2(z) \) preceding \( \Omega_1(z) \)) this will lead to reversal of the direction of motion and we will end up with a linear polarization in a horizontal direction.

Following quantum-optical STIRAP, we can write down the condition for adiabatic evolution as
\[
\int_0^L |\Omega(z)| \, dz \gg 1. \tag{7}
\]
For example, for adiabatic evolution it suffices to have
\[
\int_0^L |\Omega(z)| \, dz \gtrsim 6 \pi. \tag{8}
\]
The last condition shows that the process is robust against variation in the parameters, for example, the wavelength \( \lambda \) and the propagation length \( L \). This condition is readily fulfilled, by orders of magnitude, in many birefringent materials.

**Case B:** \( \Omega_2(z) = 0 \). Following a similar argumentation as for **Case A** and interchanging the Stokes vector components \( S_1(z) \) and \( S_3(z) \) we can write down a “dark” superposition \( \sigma(z) \) of the polarization components \( S_1(z) \) and \( S_3(z) \) of the Stokes vector,
\[
\sigma(z) = \frac{\Omega_1(z)S_2(z) + S_3(z)\Omega_2(z)}{|\Omega(z)|}. \tag{9}
\]
If initially the light is linearly polarized, \( S(z_i) = (1, 0, 0) \), then by arranging \( \Omega_1(z) \) to precede \( \Omega_3(z) \), we end up with a right circular polarization, \( S(z_f) = (0, 0, 1) \), as depicted by the north pole on the Poincaré sphere in Fig. 1(b), because the polarization superposition \( \sigma(z) \) has the asymptotic values
\[
S_1(z_i) \xrightarrow{\rightarrow} \sigma(z) \xrightarrow{\rightarrow} S_3(z_f). \tag{10}
\]
The process is again reversible: starting with a right circular polarization, and applying \( \Omega_1(z) \) before \( \Omega_2(z) \) we end up with a linear polarization.

We note that a numerical prediction of broadband conversion from circular polarized light into linearly polarized light for the wavelength range 434 nm to 760.8 nm for crystalline quartz was made by Darshit et al. \[19\]. Here this effect emerges as a special case of our general adiabatic frame of STIRAP analogy.

The adiabatic polarization conversion could be demonstrated with a single-mode fiber, which exhibits both stress-induced linear birefringence and circular birefringence (either by the Faraday effect or by a torsion of the fiber) \[1\]. Possible implementations are depicted in Figs. 2 (for Case A) and 3 (for Case B).

The technique proposed here is not limited to linear-linear or circular-linear conversions, but it is also applicable for arbitrary transformations of light polarization. For example the conversion between right circular and left circular polarization is analogous to adiabatic passage via a level crossing \[15\]. To this end, we first start up with \( \Omega_1(z) \), then we activate \( \Omega_2(z) \), then let \( \Omega_1(z) \) change sign while \( \Omega_2(z) \) is having its maximal value, and then gradually make \( \Omega_2(z) \) to fade away.

We can also change the polarization from linear to elliptical if we first begin with \( \Omega_3(z) \), then we activate \( \Omega_2(z) \), and then let \( \Omega_1(z) \) and \( \Omega_3(z) \) simultaneously fade away [cf. Eq. (9)]; this sequence is known in quantum optics as fractional STIRAP \[20\].

**V. EXACT SOLUTION**

As an example of polarization conversion we present here an exact analytic solution to the Stokes polarization equation \[11\] for the slowly varying birefringence components given by trigonometric functions:
\[
\Omega_1(z) = \Omega_0 \sin(z \pi/L), \tag{11a}
\]
\[
\Omega_3(z) = \Omega_0 \cos(z \pi/L). \tag{11b}
\]
We assume that initially the Stokes vector is \( S(z = 0) = (0, 0, 1) \), i.e. the polarization is right circular. Then the solution for the Stokes vector components as a function...
of $z$ reads

$$S_1(z) = \frac{\Omega_0^2 L^2 + \cos \left( \frac{\pi z \sqrt{L^2 + \Omega_0^2}}{L} \right)}{1 + \Omega_0^2 L^2} \sin \left( \frac{\pi z}{L} \right)$$

$$- \frac{\sin \left( \frac{\pi z \sqrt{L^2 + \Omega_0^2}}{L} \right)}{\sqrt{1 + \Omega_0^2 L^2}} \cos \left( \frac{\pi z}{L} \right),$$

$$S_2(z) = \frac{2\Omega_0 L}{1 + \Omega_0^2 L^2} \sin^2 \left( \frac{\pi z}{2} \sqrt{L^2 + \Omega_0^2} \right),$$

$$S_3(z) = \frac{\Omega_0^2 L^2 + \cos \left( \frac{\pi z \sqrt{L^2 + \Omega_0^2}}{L} \right)}{1 + \Omega_0^2 L^2} \cos \left( \frac{\pi z}{L} \right)$$

$$+ \frac{\sin \left( \frac{\pi z \sqrt{L^2 + \Omega_0^2}}{L} \right)}{\sqrt{1 + \Omega_0^2 L^2}} \sin \left( \frac{\pi z}{L} \right),$$

where $L = 1/L$. The adiabatic evolution takes place when $\Omega_0 L \gg 1$.

For $z = L/2$ (quarter period) we have

$$S_1(L/2) = \frac{\Omega_0^2 L^2 + \cos \left( \frac{\pi \sqrt{1 + \Omega_0^2 L^2}}{L} \right)}{1 + \Omega_0^2 L^2} \Omega_0 L \gg 1,$$

$$S_2(L/2) = \frac{2\Omega_0 L}{1 + \Omega_0^2 L^2} \sin^2 \left( \frac{\pi}{4} \sqrt{1 + \Omega_0^2 L^2} \right) \Omega_0 L \gg 1,$$

$$S_3(L/2) = \frac{\sin \left( \frac{\pi \sqrt{1 + \Omega_0^2 L^2}}{L} \right)}{\sqrt{1 + \Omega_0^2 L^2}} \Omega_0 L \gg 1.$$
