Fermi level position, Coulomb gap, and Dresselhaus splitting in (Ga,Mn)As

Carrier-induced nature of ferromagnetism in a ferromagnetic semiconductor, (Ga,Mn)As, offers a great opportunity to observe novel spin-related phenomena as well as to demonstrate new functionalities of spintronic devices. Here, we report on low-temperature angle-resolved photoemission studies of the valence band in this model compound. By a direct determination of the distance of the split-off band to the Fermi energy \(E_F\) we conclude that \(E_F\) is located within the heavy/light hole band. However, the bands are strongly perturbed by disorder and disorder-induced carrier correlations that lead to the Coulomb gap at \(E_F\), which we resolve experimentally in a series of samples, and show that its depth and width enlarge when the Curie temperature decreases. Furthermore, we have detected surprising linear magnetic dichroism in photoemission spectra of the split-off band. By a quantitative theoretical analysis we demonstrate that it arises from the Dresselhaus-type spin-orbit term in zinc-blende crystals. The spectroscopic access to the magnitude of such asymmetric part of spin-orbit coupling is worthwhile, as they account for spin-orbit torque in spintronic devices of ferromagnets without inversion symmetry.

Since the elaboration of the way of its preparation\(^1\), manganese-doped gallium arsenide, (Ga,Mn)As, has been the most intensively studied dilute magnetic semiconductors for two interrelated reasons\(^2,3\). First, Mn ions substituted for Ga act as an acceptor and provide holes, which mediate the ferromagnetic interaction among localized Mn moments. The presence of randomly distributed acceptors leads to a substantial disorder and to metal-to-insulator transition (MIT) in the range of hole densities relevant to ferromagnetism. Interplay of carrier-mediated exchange interactions and quantum Anderson-Mott localization results in striking properties, often difficult to describe quantitatively either analytically or by the state-of-the-art \textit{ab initio} methods. This has opened a room for extensive qualitative debates on the character of states in the vicinity of the Fermi energy and on the mechanism accounting for ferromagnetism in this system\(^4,5\).

Second, because of the novel carrier-induced nature of ferromagnetism as well as the compatibility with well-established GaAs-based devices, (Ga,Mn)As and related compounds have become a platform on which a number of new concepts of spintronic devices has been demonstrated\(^2,3\). In one kind of these devices carrier-concentration dependent ferromagnetism (e.g., spin-FET\(^6\) or spin p-i-n diode\(^7\)) or the presence of spin current (e.g., spin-LED\(^8\) and related spin-injection devices\(^9\), domain-wall displacement\(^10\)) was exploited. In another type of functional structures the direction of the magnetization vector was altered\(^11\) via spin-orbit coupling originating from the electric field brought about either by intra-atomic potentials\(^\text{16-19}\) (and giving rise to splitting between heavy/light hole (\(Γ_8\)) and split-off (\(Γ_7\)) valence-band subbands in zinc-blende semiconductors) or by inversion asymmetry leading to the presence of Dresselhaus terms in the band dispersion \(E(\mathbf{k})\)\(^15,18,20\). Tunnelling anisotropic magnetoresistance\(^21\) is one more example of devices demonstrated first for (Ga,Mn)As.

Photoemission spectroscopy, and its angle-resolved version that we employ in this work have already provided a number of important information, particularly on hybridization of Mn d-levels and valence-band p-states, and the associated participation of d-states in the wave function of carriers at the Fermi level $E_F$ in (Ga,Mn)As\(^{22-26}\). These studies have also brought into light issues associated with surface contamination.

In this work, we at first provide information on samples preparation, protocols implemented to avoid contamination as well as on experimental procedure employed in our studies of (Ga,Mn)As by angle-resolved photoemission spectroscopy (ARPES). The obtained spectra are presented, together with results of tight-binding computations. This comparison allows us to assign particular features to individual valence-band subbands, and to demonstrate that $E_F$ is located within the heavy/light hole band in ferromagnetic (Ga,Mn)As. At the same time, density of states (DOS) is considerably depleted at $E_F$, which we take as new evidence for the presence of the Coulomb gap, driven by disorder-enhanced carrier correlations, as predicted by Altshuler and Aronov\(^{27}\). By studying a series of samples we have found that the lower Curie temperature $T_C$, the larger DOS depletion, i.e., $T_C$ decreases with approaching the MIT. It is emphasized that such a Coulomb gap cannot be reproduced by the current $ab$ initio method, since it results from quantum interference of carrier-carrier interaction amplitudes at the mesoscopic scale; therefore the experimental output on the Coulomb gap is of particular importance. Another new effect revealed by our studies is magnetic linear dichroism (MLD), particularly well resolved for the split-off subband. By direct computations of light absorption for transitions from this band to free-electron states we demonstrate that MLD originates from the Dresselhaus spin-orbit terms, and is present for both s and p light polarization. This is intriguing since the MLD observed in ferromagnets by core-level photoemission\(^{28}\) is active only for p-polarization\(^{29}\).

Results

Samples and experimental. (Ga,Mn)As films with 25-nm thickness were grown by the molecular beam epitaxy (MBE) method\(^1\), and then transferred to the ARPES chamber without being exposed to the air by using a portable ultrahigh vacuum (UHV) chamber, which keeps $10^{-9}$ Torr during the transportation (see Methods). This procedure has proved very effective to obtain reliable ARPES data because ARPES is very sensitive to the condition of sample surface\(^{22}\).

The properties of (Ga,Mn)As are strongly affected by the growth conditions during MBE\(^{30}\). To avoid the formation of MnAs precipitates, it is necessary to grow (Ga,Mn)As below 250 °C (ref. 1), while the low-temperature growth likely produces anti-site As defects acting as double-donors\(^{31}\). It is also known that Mn atoms in GaAs occupy either the Ga sites or the interstitial positions\(^{32}\). Ga-substitutional Mn provides a hole by acting as an acceptor, while the interstitial Mn compensates holes by acting as a double-donor and its magnetic moment couples antiferromagnetically with that of the substitutional Mn\(^{33}\). To obtain higher metallicities of films, one needs to grow (Ga,Mn)As with less amount of interstitial Mn atoms, whose formation energy decreases with increasing Mn content\(^{34}\). Although the post-annealing of films effectively removes the interstitial Mn atoms, the annealing alternately causes precipitation of Mn atoms and/or Mn-related compounds at the surface\(^{35}\). Because ARPES is a very surface-sensitive technique, it is crucial to exclude these extrinsic factors that distort ARPES results.

We have grown 25-nm-thick Ga\(_{0.95}\)Mn\(_{0.05}\)As layers with nominal Mn compositions $x$ between 0.05 and 0.07 on an n$^+$-GaAs (001) substrate through a 100-nm thick n$^+$-GaAs buffer layer at the growth temperature between 230 and 245 °C. Magnetic characterization has been performed after the ARPES measurements, and a typical temperature dependence of in-plane magnetization of (Ga,Mn)As with a relatively high $T_C$ above 100 K is presented in Fig. 1a. We find that the higher growth temperature tends to result in the higher values of $T_C$. We prepared a series of (Ga,Mn)As films with $T_C$ between 35 and 112 K in the as-grown state. A reference n-type GaAs film doped with Si concentration of $10^{19}$ cm$^{-3}$ has been grown on an n$^+$-GaAs (001) substrate in the same MBE chamber.

Location of the Fermi level. Figure 1c shows the experimental band structure of Ga\(_{0.95}\)Mn\(_{0.05}\)As ($T_C$ = 101 K) along the $\Gamma$X cut obtained by plotting the ARPES-spectral intensity as a function of binding energy and wave vector. We have measured ARPES spectra with the He-I\(_{α}\) resonance line ($h\nu$ = 21.218 eV) with the main polarization vector along the $\Gamma$X cut (Fig. 1b) at temperature $T$ = 30 K. We observe three dispersive hole-like bands (A-C) centred at the $\Gamma$ point, all of which are ascribed mostly to the As 4p orbitals in GaAs\(^{36}\) and also in (Ga,Mn)As\(^31\). Band A has the top of dispersion at the binding energy of 2.9 eV. Bands B and C tend to converge on the very surface-sensitive technique, it is crucial to exclude these extrinsic factors that distort ARPES results.

We compare in Fig. 1e the experimental band structure with our tight-binding calculations for GaAs (see Methods) along the $\Gamma$KX ($k_z$ = 0, solid curves) and X$\Gamma$X ($k_z$ = $2\pi/a_0$, dashed curves) high-symmetry lines. There are good correspondences between the experiment and the calculation. Comparison shows that bands B and C are assigned to the bands at $k_z$ = 0, while bands A and D are at $k_z$ = $2\pi/a_0$. This suggests that the ARPES data reflect the electronic states averaged over a wide $k_z$ region in the bulk Brillouin zone, so that the electronic states along the high-symmetry lines, i.e. at $k_z$ = 0 and $2\pi/a_0$, have a dominant contribution to the total “one-dimensional” DOS averaged over $k_z$\(^{26,37}\). Therefore, the overall agreement between the experimental and the calculated dispersions as seen in Fig. 1e leads us to conclude that bands B and C are the split-off (SO) and light-hole (LH) bands, respectively.

We have investigated the detailed band structure near $E_F$ at the $\Gamma$ point. As displayed in Fig. 2a, band B shows a “$\Lambda$”-shaped spectral-intensity distribution. To see the dispersive feature more clearly, we have subtracted the
featureless background from the raw spectrum (Fig. 2b), and show the result and its intensity plot in Fig. 2c,d, respectively. Intriguingly, a clear Fermi-edge structure is recognized in the spectrum when the band approaches $E_F$ (Fig. 2c). It is noted that a similar Fermi-edge-like structure is already seen even in the raw spectrum (Fig. 2b), indicating its intrinsic nature. It is stressed here that the present first observation of the Fermi edge in (Ga,Mn)As is a consequence of the careful surface treatment using the UHV sample transfer chamber as well as the high-energy resolution in the ARPES measurement. As seen in Fig. 2c, the spectral intensity at the Fermi edge...
systematically increases when band B approaches $E_F$, as highlighted by the MDC at $E_F$ (white curve in Fig. 2d).

We also observed a similar spectral characteristics in another (Ga,Mn)As sample with lower $T_C$ of 62 K (Fig. 2e,f).

As shown in Fig. 2g, band B in both samples with $T_C = 62$ K or 101 K shows a good correspondence to the SO band lying ~0.35 eV below the LH/HH (heavy hole) band at the $\Gamma$ point in GaAs. Thus, the present ARPES results unambiguously demonstrate that the Fermi level resides deeply inside the As-$4p$ valence band. This conclusion is in accord with recent on-Mn resonance photoemission studies$^{23,24}$ which confirm that the main spectral weight of Mn $d$ states is at 3.5 eV below $E_F$. Accordingly, taking also into account a large difference in the concentration of As and Mn, a local $d$-weight maximum below $E_F$ accounts for only a few percent of the total one-particle DOS in this region.

The hole-doped nature of the valence-band states is also corroborated by a comparison of the experimental band structure between (Ga,Mn)As with $T_C = 62$ K (Fig. 2f) and nonmagnetic n-type GaAs (n-GaAs) doped with Si at concentration of 10$^{19}$ cm$^{-3}$ (Fig. 2h). The doped electron concentration of 10$^{19}$ cm$^{-3}$ results in the surface depletion layer with a thickness of several tens of nm, which is much thicker than the probing depth with the He I$\alpha$ line in ARPES measurements. Hence, when discussing the binding energy in n-GaAs one needs to take into account the band bending effect at the surface, which is ineffective for metallic (Ga,Mn)As with a depletion layer less than 1 nm. By shifting the chemical potential of n-GaAs upward by ~0.9 eV below the LH/HH (heavy hole) band at the $\Gamma$ point in GaAs. Thus, the present ARPES results unambiguously demonstrate that the Fermi level resides deeply inside the As-$4p$ valence band. This conclusion is in accord with recent on-Mn resonance photoemission studies$^{23,24}$ which confirm that the main spectral weight of Mn $d$ states is at 3.5 eV below $E_F$. Accordingly, taking also into account a large difference in the concentration of As and Mn, a local $d$-weight maximum below $E_F$ accounts for only a few percent of the total one-particle DOS in this region.

The hole-doped nature of the valence-band states is also corroborated by a comparison of the experimental band structure between (Ga,Mn)As with $T_C = 62$ K (Fig. 2f) and nonmagnetic n-type GaAs (n-GaAs) doped with Si at concentration of 10$^{19}$ cm$^{-3}$ (Fig. 2h). The doped electron concentration of 10$^{19}$ cm$^{-3}$ results in the surface depletion layer with a thickness of several tens of nm, which is much thicker than the probing depth with the He I$\alpha$ line in ARPES measurements. Hence, when discussing the binding energy in n-GaAs one needs to take into account the band bending effect at the surface, which is ineffective for metallic (Ga,Mn)As with a depletion layer less than 1 nm. By shifting the chemical potential of n-GaAs upward by ~0.9 eV below the LH/HH (heavy hole) band at the $\Gamma$ point in GaAs. Thus, the present ARPES results unambiguously demonstrate that the Fermi level resides deeply inside the As-$4p$ valence band. This conclusion is in accord with recent on-Mn resonance photoemission studies$^{23,24}$ which confirm that the main spectral weight of Mn $d$ states is at 3.5 eV below $E_F$. Accordingly, taking also into account a large difference in the concentration of As and Mn, a local $d$-weight maximum below $E_F$ accounts for only a few percent of the total one-particle DOS in this region.
Numerical simulation of the ARPES spectrum (blue solid curve) for (Ga,Mn)As with E features of (Ga,Mn)As provided the magnitude of expectations, experimental and theoretical studies of millikelvin conductance in various dimensionality structure dependence of electric conductance at low temperatures belongs to this category. In agreement with these plotted as a function of renormalization group theory45,48, should result in a sizable decrease of DOS at energy region of the gap. ARPES spectrum of gold (Au) which shows a sharp Fermi-edge cut-off as seen in Fig. 3a. This rounded feature of spectrum provides a new evidence for a depression of one-particle DOS at (Au) which shows a sharp Fermi-edge cut-off as seen in Fig. 3a. This rounded feature of spectrum provides a new

Coulomb gap. Having established the position of the Fermi energy in the As 4p valence band in (Ga,Mn)As, the next question is how the metallic state evolves from pristine GaAs by Mn doping. To address this question, we performed systematic ARPES measurements on a variety of samples with different Tc's. Figure 3a shows a set of ARPES spectra at the Γ point revealing a rounded shape in the vicinity of E_F unlike typical metals such as gold (Au) which shows a sharp Fermi-edge cut-off as seen in Fig. 3a. This rounded feature of spectrum provides a new evidence for a depression of one-particle DOS at E_F in (Ga,Mn)As, so far seen by tunnelling spectroscopy and assigned to the electron-electron correlation in the vicinity to a disorder-driven MIT41–43.

According to the Altshuler-Aronov theory27,44, the interaction-induced correction to single-particle DOS in a three-dimensional metal assumes the form $\rho(E) = a + b|\epsilon|^2$ at $k_B T < |\epsilon| < h/\tau < E_F$, where $\epsilon$ is the quasiparticle energy with respect to $E_F$, and $\tau$ is the momentum relaxation time. The sign and magnitude of $a$ and $b$ are determined by mutually compensating interference effects in the singlet and triplet particle-hole diffusion channels42–44. However, spin–disorder scattering in a paramagnetic phase or large band spin-splitting in a ferromagnetic phase destroy the interference in the triplet channel, which according to the perturbation45,47 and dynamic renormalization group theory46,48, should result in a sizable decrease of DOS at $E_F$, i.e., $a < 0$, $b > 0$, and $\nu(0) \rightarrow 0$ on approaching the MIT from the metal side.

As shown in Fig. 3a, a numerically simulated ARPES spectrum with taking into account the expected form of the DOS depression, $\rho(E) = a + b|\epsilon|^2$, where $a < 0$ and $b > 0$ reproduces satisfactorily the experimental spectrum up to ~0.1 eV relative to $E_F$ (Fig. 3b). This value coincides well with the energy at which the tunnelling DOS starts to be depleted43 and also the optical conductivity is peaked49, suggesting that the suppression of DOS near $E_F$ is an inherent feature of ferromagnetic (Ga,Mn)As. We observe a monotonic decrease of the near-$E_F$ spectral weight upon decreasing $T_C$. This is more clearly visible by plotting the DOS at $E_F$, i.e., $\nu(0)$ as a function of $T_C$ (Fig. 3b), demonstrating a close relationship between the proximity to MIT, $T_C$, and $\nu(0)$. Accordingly, an effect from the soft Coulomb gap should be considered when discussing the one-particle excitations. At the same time, many important physical parameters are determined by the thermodynamic DOS which in terms of the hole concentration $p$ assumes the form $\rho(E_p) = -\partial p/\partial E_p$, so that its magnitude is only weakly perturbed by disorder and carrier correlations on the metallic side of the MIT. According to the theoretical predictions45,47, the temperature dependence of electric conductance at low temperatures belongs to this category. In agreement with these expectations, experimental and theoretical studies of millikelvin conductance in various dimensionality structures of (Ga,Mn)As provided the magnitude of $\rho(E_F)$ close to that expected for holes in an unperturbed valence band of GaAs (ref. 50). The present ARPES results thus unambiguously demonstrate that (Ga,Mn)As with high
TC possesses the metallic electronic structure with the Fermi level in the valence band, and is strongly influenced by the conjunction of correlation and disorder effects.

Magnetic linear dichroism. We now turn our attention to the “magnetic linear dichroism” (MLD) effect in the ARPES intensity of the valance band in (Ga,Mn)As (for details of the MLD measurements, see Methods). According to Fig. 4a,b the symmetry of the ARPES intensity with respect to the Γ point shows a magnetization-direction dependence in (Ga,Mn)As with TC = 101 K. As shown in Fig. 4a, the near-E_F photoelectron intensity of the SO band in the ferromagnetic phase (T = 30 K) in the k[110] region (left-hand side, negative k values) is stronger than that in the k[110] region (right-hand side) when we magnetize the sample along the [100] direction as illustrated in Fig. 4c (see also Fig. 2d,f). On the other hand, when we reverse the magnetization direction to [100] the photoelectron intensity in the positive k region becomes more dominant (Fig. 4b). The intensity difference between two opposite magnetization cases is estimated to be 2–8% (depending on the binding energy) by taking account of background contribution of ~70%. When we overlaid the band dispersion for two magnetization cases, we recognize a finite difference in their energy positions as shown in Fig. 4d. Interestingly, when we

Figure 4. Magnetization dependence of ARPES intensity in (Ga,Mn)As. (a,b) Near-E_F ARPES intensity at T = 30 K of (Ga,Mn)As with TC = 101 K, magnetized along the [100] and [100] directions, respectively. Calculated band dispersion of (Ga,Mn)As with incorporating the exchange splitting57 is shown with yellow curves for comparison. (c) Experimental geometry of sample axes, magnetization direction, and incident photons. Solid and dashed rectangles indicate the plane of incidence (110) and the emission plane of photoelectrons (110), respectively. (d) Location of the energy band extracted from the peak positions of the momentum distribution curves (MDCs) in (a,b). (e) Same as (a,b) but with zero-field (z.f.) cooling. (f) Near-E_F ARPES intensity at T = 30 K of GaAs (n-type; Si-doped).
cool down the sample without external magnetic field, the intensity asymmetry becomes less clear (Fig. 4e). In addition, the asymmetry is not seen in nonmagnetic n-GaAs (Fig. 4f).

In order to determine the origin of this MLD we note that for the valence-band photoemission in question, photon-induced transitions occur between the extended valence band states (SO band in our case) and the free-electron-like states which propagate towards the detector in the vacuum while damped inside the crystal (the one-step model). Since there is no periodicity in the direction normal to the surface, \( k_z \) is not conserved. Therefore valence states with various \( k_z \) can contribute to the magnitude of emitted photocurrent at given \( E_{\text{kin}} \) and \( k_y \) values. Hence, following the method elaborated previously\(^5\), we have calculated for a given orientation of \( k_z \) and energy \( E_{\text{SO}} \) in the SO band the absorption coefficient for linearly polarized light considering electric-dipole transitions from the SO band split by the \( p-d \) exchange and spin-orbit interactions to spin-degenerate free-electron states. Since only \( k_z \) is conserved, the absorption coefficient for four possible transitions is a product of corresponding DOS \( \nu(E_{\text{SO}}) = k_f^2(2\pi^2\delta E_{\text{SO}}/\delta k_z)^{-1} \) at \( k_z = 0 \) and the square of the absolute value of the matrix element averaged over \( k_z \) values. No MLD is found if the valence band is described within the six band Luttinger model\(^1\). In contrast, allowing for the presence in the \( 6 \times 6 kp \) Hamiltonian of terms brought about by the inversion asymmetry\(^2\), MLD of characteristics observed experimentally shows up. There are three such contributions in the case under consideration: terms proportional to \( k^3 \), originally introduced by Dresselhaus for zinc-blende crystals, and two components linear in \( k \), appearing under biaxial and shear strain, respectively. In the absence of the exchange splitting, time reversal symmetry leads to the same magnitude of photoemission for \( k \) and \( -k \) if transitions from both spin subbands are taken into account. However, this is no longer the case if time reversal symmetry is broken by non-zero magnetization.

Figure 5 shows the computed magnitude of MLD = \( (A_{||}[110] - A_{||}[\overline{1}0\overline{0}]) / A_{||}[110] \) at \( M \parallel [100] \) for the SO band as well as for \( kp \) parameters specified in Methods\(^4\) and for the expected values of strain\(^4 \) \( \varepsilon_{\text{xx}} = -0.4\% \) and \( \varepsilon_{\text{yy}} = 0.1\% \) as well as for the magnitude exchange splitting of the valence band at \( \Gamma_8 \) point \( \Delta_v = 180 \text{ meV} \), corresponding to the saturation magnetization for \( x = 0.05 \). Since the character of light polarization is uncertain under our experimental conditions, the calculations have been performed for both \( s \) and \( p \) polarization. We have found that for the employed parameters, the \( k^3 \) contribution dominates. As seen, the computed magnitude of the average value of MLD over the two polarization is in accord with experimental results, i.e., the theory predicts properly the sign, magnitude, and energy width of the effect as well as its symmetry, \( A_{||}[110](M \parallel [100]) = A_{||}[\overline{1}0\overline{0}](M \parallel [\overline{1}0\overline{0}] ) \). It is worth noting that to resolve directly spin splitting and \( k \) asymmetry of the valence-band subbands ultra-high-resolution spin-resolved ARPES measurements would be necessary.

Conclusions

To conclude, our ARPES studies of (Ga,Mn)As resolve particularly well the band split off by spin-orbit coupling (i.e., \( \Gamma_7 \) valence band subband at \( k = 0 \)). Since the magnitude of spin-orbit splitting is known quite precisely and varies little across the arsenide family of III-V compounds, we have been able to evaluate quite accurately the position of the Fermi level with respect to the top of the valence band. The obtained Fermi energy of about \(-0.3 \text{ eV} \) in (Ga,Mn)As with \( T_c \) of the order of 100 K is consistent with the \( p-d \) Zener model\(^1\). At the same time our data point to the presence of a substantial depression in DOS at \( E_F \). We assign this observation, in accord with tunnelling studies\(^4\) to electron correlation in disordered systems, which result in a depletion of DOS for the universality class in question\(^2\). We have also detected magnetic linear dichroism that results from inversion asymmetry of zinc-blende structure. Our computations within \( kp \) theory shows that a dominant contribution to
the magnitude of MLD in the SO band comes from cubic $k^3$ terms. It would be interesting to check their contribution to spin-orbit torque analysed so-far considering only linear terms in $k$ (refs 13–15).

**Methods**

**Sample preparation and ARPES experiments.** 25-nm thick Ga$_{1-x}$Mn$_x$As films with $x$ between 0.05 and 0.07 were grown at substrate temperature between 230 and 245°C on n$^+$-GaAs (001) substrate through a 100-nm thick n$^{-}$-GaAs buffer layer grown at ~560°C by molecular beam epitaxy (MBE). After the growth, we immediately transferred the films to a portable ultrahigh-vacuum (UHV) chamber equipped with non-evaporating getter and ion pumps, disconnected the portable chamber from the MBE system, and then connected to the ARPES system with keeping the UHV condition better than 5 × 10$^{-10}$ Torr. All the sample-transfer procedures were carried out within one hour. ARPES measurements were performed with the MBS-A1 electron analyzer equipped with a high-intensity He plasma discharge lamp. We use the He-I resonance line (photoenergy: $h\nu = 21.218$ eV) to excite photoelectrons. The energy resolution for the ARPES measurements was set at 15–40 meV. The sample temperature was kept at 30 K during the measurements.

For the MLD measurements, first we cooled down the sample to $T = 30$ K without magnetic field in the UHV chamber directly connected to the ARPES chamber with μ-metal shielding (~0.5 μ(T)). Next, we magnetized the (Ga,Mn)As thin film ($T_C = 101$ K) by approaching the bar-shaped neodymium magnet to align its magnetic field parallel to the magnetization easy axis of the sample, [100] or [100]. It is noted that this easy axis is indicated by the observation of sizable magnetization and smooth temperature dependence of the magnetization curve at the remanent magnetic state in Fig. 1a. After the magnetization, we transferred the sample to the ARPES chamber with keeping the sample temperature at 30 K, and measured the MLD data without external magnetic field (Fig. 4a,b). For the zero-field cooling measurement (Fig. 4e), we demagnetized the sample in the ARPES chamber by increasing the temperature up to 150 K (above $T_C$), and then slowly cooled down to $T = 30$ K.

**Calculations.** A tight-binding method described previously$^{24}$ was employed to determine the band structure $E(k)$ of GaAs and Ga$_{0.99}$Mn$_{0.01}$As in the whole Brillouin zone. Density of states and matrix elements for electric-dipole optical transitions between split-off band ($\Gamma_7$ at $k=0$) and free electron states were computed from the six band Luttinger-Kohn $kp$ theory with the standard values$^{34}$ of the Luttinger parameters, the $p-d$ exchange integral $\beta$, and the elastic moduli $c_{ij}$ taking additionally into account odd in $k$ terms resulting from inversion asymmetry of the zinc-blende structure. The numerical values of $kp$ parameters ($b_{11} = -58.71$ eVÅ$^2$, $b_{11} = -81.93$ eVÅ$^2$, and $b_{11} = -101.9$ eVÅ$^2$), describing the dominant $k^3$ terms, are taken from ref. 53. There are additional two contributions to the six band $kp$ Hamiltonian linear in $k$, contributing also to the sector of the $kp$ Hamiltonian describing the split-off band $H_{\Gamma_7}$. These terms are generated by shear $\varepsilon_i$ and diagonal $\varepsilon_i$ strain tensor components that enter into $H_{\Gamma_7}$ via $\sigma \cdot \phi$ and $\phi$, respectively$^{34}$, where $\sigma$ are Pauli matrices, $\phi = k_{xy} - k_{yz}$, and $\psi = k_{xy} - k_{yx}$ (and cyclic permutations). The form of the six band Hamiltonian involving $\psi$ and the corresponding deformation potential constant $C_{ij}$ is $-2.2 \times 10^6$ m/s were given previously$^{34}$. The magnitude of the deformation potential describing the term with $\psi$ is unknown. Following a previous approach$^{15}$, the same value of the deformation potential and also the same form of the Hamiltonian (with $\phi$ replaced by $\psi$) are adopted. In the case under consideration $\varepsilon_x = 0$, $\varepsilon_y = \varepsilon_z = 0$, and $\varepsilon_x = \varepsilon_y = \varepsilon_{zx} = 0$, where $x$ is taken along the growth direction$^{15,53}$.
