Functional Consequence of Covalent Reaction of Phosphoenolpyruvate with UDP-N-acetylglucosamine 1-Carboxyvinyltransferase (MurA)*

Received for publication, January 13, 2012, and in revised form, February 27, 2012 Published, JBC Papers in Press, February 29, 2012, DOI 10.1074/jbc.M112.342725

The enzyme MurA has been an established antibiotic target since the discovery of fosfomycin, which specifically inhibits MurA by covalent modification of the active site residue Cys-115. Early biochemical studies established that Cys-115 also covalently reacts with substrate phosphoenolpyruvate (PEP) to yield a phospholactoyl adduct, but the structural and functional consequences of this reaction remained obscure. We captured and depicted the Cys-115-PEP adduct of Enterobacter cloacae MurA in various reaction states by X-ray crystallography. The data suggest that cellular MurA predominantly exists in a tightly locked complex with UDP-N-acetylmuramic acid (UNAM), the product of the MurB reaction, with PEP covalently attached to Cys-115. The uniqueness and rigidity of this “dormant” complex was previously not recognized and presumably accounts for the failure of drug discovery efforts toward the identification of novel and effective MurA inhibitors. We demonstrate that recently published crystal structures of MurA from various organisms determined by different laboratories were indeed misinterpreted and actually contain UNAM and covalently bound PEP. The Cys-115-PEP adduct was also captured in vitro during the reaction of free MurA and substrate UDP-N-acetylgalactosamine or isomer UDP-N-acetylglucosamine. The now available series of crystal structures allows a comprehensive view of the reaction cycle of MurA. It appears that the covalent reaction of MurA with PEP fulfills dual functions by tightening the complex with UNAM for the efficient feedback regulation of murein biosynthesis and by priming the PEP molecule for instantaneous reaction with substrate UDP-N-acetylmuramic acid.

The enzyme MurA (UDP-N-acetylgalactosamine 1-carboxyvinyltransferase, EC 2.5.1.7) catalyzes the first step in biosynthesis of the bacterial cell wall and is critical for bacterial survival (1, 2) (Fig. 1). Inhibition of MurA by the antibiotic fosfomycin (3) or the viral maturation protein A2 (4) results in bacterial cell lysis and death. The MurA reaction proceeds through a tetrahedral intermediate of substrates UDP-N-acetylmuramic acid (UNAG) and phosphoenolpyruvate (PEP) followed by elimination of inorganic phosphate to yield the enolpyruvyl product (EP-UNAG) (5, 6). Enzyme mechanistic studies established that substrate PEP covalently reacts with the catalytically important residue Cys-115 to form a phospholactoyl adduct, suggesting that nucleophilic attack is a component of the reaction cycle (7–9). However, the discovery that Cys-115 could be replaced by an aspartate without loss of activity (a mutation found in some bacteria including Mycobacteria) led to the conclusion that Cys-115 functions as a general acid-base catalyst and not as a nucleophile in the reaction with PEP (10). Cys-115 is a member of a 10-residue loop in the N-terminal globular domain that undergoes drastic conformational changes upon binding of UNAG by approaching the interdomain cleft and positioning the Cys-115 side chain into the PEP binding site (11–15). Cys-115 has received considerable attention as the target of covalent modification by fosfomycin (12) and other electrophilic natural products such as terric acid (16) and cnicin (17). Notably, no new drug candidates of MurA have been introduced since the discovery of fosfomycin 40 years ago, indicating a lack of critical information required to successfully target this enzyme by reversible inhibitors.

Despite the extensive knowledge collected by various laboratories over the years regarding the structure-function relationships of MurA, the PEP molecule bound covalently or noncovalently to the enzyme was never depicted in molecular detail. Hence, structural and functional consequences of the

3 The abbreviations used are: UNAG, UDP-N-acetylgalactosamine; EP-UNAG, enolpyruvyl-UNAG; PEP, phosphoenolpyruvate; UNAGal, UDP-N-acetylgalactosamine; EP-UNAGal, enolpyruvyl-UNAGal; UNAM, UDP-N-acetylmuramic acid; ITC, isothermal microcalorimetry; THI, tetrahedral intermediate.
PEP interaction with MurA remained elusive. In an attempt to capture the PEP molecule in the course of reaction with MurA, we probed selected mutant enzymes and analogues of UNAG by x-ray crystallography and isothermal microcalorimetry (ITC). Through these studies we found that recombinant Enterobacter cloacae MurA isolated from E. coli expression strains exists in a tight complex with UDP-N-acetylmuramic acid (UNAM), the product of the MurB reaction, with PEP covalently bound to Cys-115. This dormant complex is extraordinarily resilient against dilution and salts commonly used in purification and crystallization but can be readily unlocked by incubation with UNAG (1 mM) or inorganic phosphate (50 mM). Without this treatment, however, MurA remains in the locked state. We demonstrate that previously published co-crystal structures of MurA from Escherichia coli, Haemophilus influenzae, and Aquifex aeolicus by three different laboratories were indeed misinterpreted and actually contain UNAM and covalently bound PEP. The rigidity of this complex presumably accounts for the failure of drug discovery efforts toward the development of reversible MurA inhibitors with antibacterial potential. Using ligand-free MurA, the Cys-115-PEP adduct was captured in two distinct reaction states with substrate or product. The now available series of crystal structures affords an unprecedented view of the individual steps of MurA catalysis in molecular detail. The findings suggest that formation of the Cys-115-PEP adduct fulfills dual functions by tightening the dormant complex with UNAM for the feedback regulation of murein synthesis and by activating the PEP molecule for catalysis.

**EXPERIMENTAL PROCEDURES**

PEP (potassium salt), UNAG, and UDP-N-acetylglactosamine (UNAGal) were purchased from Sigma. Reagents for crystallization were separately overexpressed in E. coli from the respective ligand when appropriate. The resulting eluate yielded crystallization-grade monomeric enzyme.

Protein Crystallography—After the last purification step, one third of the wild-type protein was loaded onto a PD-10 column (GE Healthcare) and eluted with 50 mM HEPES (pH 7.5). A second third of the protein was eluted into 50 mM sodium/potassium phosphate buffer (pH 6.8), and the final portion was first eluted into 50 mM sodium/potassium phosphate buffer (pH 6.8) followed by an additional PD-10 column to transfer the protein into 50 mM HEPES buffer (pH 7.5). The C115D and R120A mutant MurA proteins were directly transferred into 50 mM HEPES (pH 7.5) and 50 mM Tris (pH 8.0), respectively. All buffers used for PD-10 columns contained 2 mM DTT. Wild-type, C115D, and R120A MurA were concentrated to 72, 100, and 120 mg ml⁻¹, respectively, using Amicon centrifugal filter devices (Millipore, Billerica, MA) at 4 °C. All crystals were grown using the hanging drop vapor diffusion method at 18 °C from a 1:1 (v/v) ratio of protein (40 mg ml⁻¹ wild-type and C115D or 120 mg ml⁻¹ R120A) and reservoir solutions (Table 1). For data collection, crystals were harvested in a cryoprotectant mixture consisting of the respective reservoir composition and including 20% (v/v) ethylene glycol and 0.5 mM concentrations each of the respective ligand when appropriate.

X-ray diffraction data were recorded in the Moffitt Cancer Center Structural Biology Core at −180 °C using CuKα X-rays generated by a Rigaku Micro-Max 007-HF x-ray generator, focused by mirror optics and equipped with a Rigaku CCD Saturn 944 system, on single crystals frozen in liquid N₂. Data were reduced with XDS (18). The structures were determined by molecular replacement using MOLREP (CCP4) (19) with PDB...

Treated with 50 mM phosphate buffer before crystallization.

RESULTS AND DISCUSSION

In an attempt to capture the intact PEP molecule in the reaction of MurA, we probed wild-type and single-site-directed mutant enzymes of recombinant *E. cloacae* MurA with analogues of UNAG for co-crystallization in the presence and absence of PEP. MurA generally crystallizes in different space groups and higher oligomeric states depending on the conformation of the 10-residue loop containing Cys-115 (5, 6, 11–13, 15, 16, 22–25), which often negatively impacts the diffraction quality and feasibility of structure determination. We, therefore, broadened the spectrum of previously established crystallization conditions by subjecting the enzyme to new crystallization screening trials. The use of different buffers into which the enzyme was transferred before crystallization proved crucial to crystallization of the various enzyme-ligand complexes presented here (Table 1).

**Recombinant MurA Expressed in E. coli Exists in Tight Complex with UDP-N-Acetylmuramic Acid and PEP**—We found that *E. cloacae* MurA overexpressed in *E. coli* crystallized in the closed state with a fully occupied active site, although ligands were not present during purification or crystallization (Fig. 2A, Table 2). This result was unexpected, as we had previously crystallized the same enzyme in distinct open and ligand-free states (22). The only difference between this and our previous studies is that the enzyme was not treated with phosphate buffer before crystallization, as discussed below. The results indicate tight ligand binding within the complex, as evidenced by the extraordinary resilience of this complex against dilution during purification and in preparation for crystallization. Detailed inspection of the electron density revealed that the UNAG binding site is occupied with UNAM, the product of the MurB reaction, which was previously recognized by Berti and co-workers (26) as a potent inhibitor of MurA. Remarkably, the complex also contains a pholactoyl adduct forms multiple electrostatic interactions with positively charged residues, thereby stabilizing the loop, tightening the complex, and effectively shielding the active site from solvent (Fig. 2B).

* Rmerge = quality of amplitudes (F) in the scaled data set (29).
* r.m.s.d. = root mean square deviation from ideal values.
* Rmerge = 100 * Σ |Fobs - Fmodel|/Fobs where Fobs and Fmodel are the observed and calculated structure factor amplitudes, respectively.
* Rcryst = Rmerge calculated for randomly chosen unique reflections, which were excluded from the refinement.
* Calculated by Molprobit (30).
* Cross-validated coordinate error was calculated by CNS (31).
The Cys-115-PEP adduct of MurA was identified by biochemical methods almost two decades ago (8, 9), but the structure and physiological or mechanistic rationale behind this reaction remained elusive. Initially characterized as a covalent intermediate in the MurA reaction, the catalytic competence of the C115D mutant enzyme suggested that the covalent adduct is a mere side product of a general acid-base reaction cycle devoid of covalent intermediates (10). Our finding of a tight MurA-PEP/UNM complex indicates that the covalent reaction with PEP is of functional significance. Co-crystallization with PEP rendered the complex unchanged, whereas co-crystallization with UNAG yielded a new complex with EP-UNAG and Cys-115 free of PEP (Fig. 3A). As PEP was not present during crystallization, it appears that UNAG displaced UNAM followed by transfer of PEP from Cys-115 to UNAG and yielding EP-UNAG in a single-turnover reaction. These findings corroborate earlier biochemical studies that the Cys-PEP adduct is catalytically competent and that incubation of purified MurA with UNAG yielded enzyme free of PEP (8, 9). Using the same expression system and purification procedures, the E. cloacae C115D MurA isolated from E. coli is open and free of ligands (Fig. 3B), emphasizing the importance of the nucleophilic cysteine side chain for the formation of the dormant complex. The crystal structure of the C115D MurA was also determined with UNAG bound (Fig. 3C), revealing for the first time that the cysteine and aspartate side chains adopt similar positions and conformations in the PEP binding site (Fig. 3, D–E).

The dormant complex opens and releases both UNAM and PEP after transfer into 50 mM sodium/potassium phosphate buffer (pH 6.8). Buffers such as Tris, MES, MOPS, and HEPES as well as salts such as ammonium sulfate (up to 1M), KCI (150

- Covalent Reaction of PEP with MurA

---

**FIGURE 2.** MurA exists in a tight complex with UNAM and PEP covalently attached to Cys-115. **A**, surface representations of different states of MurA (ligand-free (VII), UNAG (VIII), and UNAM + PEP (IX)) show the closure of the active site upon covalent reaction of Cys-115 with PEP. The 2Fo – Fc electron density at 2 Å resolution and contoured at 1σ is shown as blue mesh for UNAM and adduct of the dormant complex. The C-terminal domain of MurA is colored in beige, the N-terminal domain is in green, the loop 112–121 is in magenta, and Cys-115 or the Cys-115-PEP adduct is in cyan. **B**, shown is a stereo presentation of the PEP binding site in the dormant complex with UNAM. Black dotted lines indicate hydrogen bonding or electrostatic interactions, and the green spheres are water molecules.
Inorganic phosphate is a product of the forward reaction and was previously found to be present in the PEP binding site of the C115S mutant MurA (supplemental Fig. S1) (13). High phosphate concentrations may, therefore, disrupt the complex by forcing the PEP-Cys-115 adduct of the active site, thereby opening the enzyme and releasing bound UNAM. Upon exposure to solvent and reducing agents such as DTT in the buffer, PEP is liberated from Cys-115, and the enzyme adopts the familiar open, ligand-free state. Inorganic phosphate also binds to the open enzyme state in the space normally occupied by the diphospho bridge of the UNAG molecule (22). It is possible that additional low affinity phosphate binding sites exist that influence the stability of the dormant complex. However, the data suggest that cellular levels of inorganic phosphate are not sufficient to unlock the complex.

Previously Released Crystal Structures of MurA from Different Organisms Were Misinterpreted

Previously we and others were unaware of the effect of inorganic phosphate on purified MurA to yield free enzyme. Our own studies (5, 11, 13–16, 22, 23, 27) were performed with enzyme routinely transferred into phosphate buffer in the preparation for structural (small angle x-ray scattering and crystallography) and biochemical (kinetics and fluorescence) experiments, enabling characterization of
the distinct open and closed states of the enzyme. As structural studies of MurA by other laboratories did not involve treatment with phosphate before crystallization, we questioned whether crystal structures of MurA deposited in the PDB indeed contained the ligands as claimed or if the same MurA-PEP/UNAM complex had been crystallized unknowingly. We thoroughly reinvestigated the recently deposited crystal structures of *E. coli* MurA liganded with UNAM and phosphite (PDB code 3ISS (25)), *H. influenzae* MurA liganded with UNAG and sulfate (PDB code 2RL1 (24)), and *A. aeolicus* MurA liganded with EP-UNAG and phosphate (PDB code 2YVW, no associated publication). Using the deposited structure factors along with the respective coordinate sets, we performed refinement cycles in the presence and absence of ligands (Table 3). The results clearly demonstrate that the electron density of the respective active sites had previously been misinterpreted (Fig. 4). Each structure contains UNAM, and the originally assigned anions actually represent the phosphate group of covalently bound PEP. Combined, these findings indicate that MurA from various bacterial species exist predominantly in a dormant state under physiological conditions, supporting the previously proposed role of UNAM as a feedback inhibitor of murein biosynthesis and revealing a new function of PEP by locking the MurA-UNAM complex.

**Cys-115-PEP Adduct Also Forms with UNAG Analogues and Mutant Enzymes**—We next asked if the Cys-115-PEP adduct could also be generated *in vitro* by incubating ligand-free (phosphate-treated) MurA with PEP and UNAGal, an isomer of UNAG. The resulting crystal structure contained EP-UNAGal and PEP covalently bound to Cys-115 (Fig. 5). The covalent adduct adopts the same conformation as in the dormant complex with UNAM, and the conformation of EP-UNAGal is identical to that of EP-UNAG, suggesting a single turnover or very slow reaction. The 4'-OH group of UNAGal interacts more favorably with the side chain of Asp-305, which may hinder product release. Interestingly, the crystal structure also shows that a single UNAGal molecule is bound outside the PEP binding site interacting with the Cys-115-PEP adduct through coordination with a Mg²⁺ ion (supplemental Fig. S3). Using the same conditions, MurA failed to crystallize in the presence of UNAG and PEP presumably due to the microheterogeneity arising from the various enzyme states interchanging rapidly reversible with substrates and products.

MurA did not display appreciable catalytic activity with UNAGal as a substrate, and direct binding studies using ITC support the crystallographic observations (Fig. 6). With a dissociation constant of 124 μM, UNAGal binds to free wild-type MurA ~2-fold less efficiently than UNAG (K_d = 50 μM, as
Covalent Reaction of PEP with MurA

The Cys-115-PEP adduct was also captured using the R120A mutant of MurA after incubation with UNAG and PEP (Fig. 5B). This mutant enzyme is catalytically incompetent and accumulates UNAG in the active site instead of EP-UNAG. PEP is covalently bound to Cys-115, and the loop adopts a slightly different conformation. The lack of the Arg-120 side chain allows Arg-91 to migrate into the active site and interact with the Cys-115-PEP adduct, possibly obstructing the transfer of PEP from Cys-115 to UNAG. The data suggest that in the wild-type enzyme, Arg-120 may donate a proton to the thiol group of the covalent adduct, such that Cys-115 becomes a good leaving group for the transfer of PEP to UNAG (Fig. 5C).

Reaction of Most MurA Enzymes Likely Proceeds through Cys-115-PEP Adduct—Taken together, the findings suggest that the reaction of PEP with Cys-115 holds significance for the function and regulation of MurA in the cell. The information gained from our crystal structures as well as those determined previously enable a comprehensive picture of the MurA reaction in atomic detail (Figs. 7 and 8). The existence of distinct complexes of MurA with PEP covalently attached to Cys-115 support the original proposal from the Wanke and Amrhein (9) and Anderson and co-workers (8) laboratories that the covalent adduct is a regular reaction intermediate.

The data suggest that cellular MurA exists predominantly in the dormant complex (I), which reacts in a rapidly reversible manner with UNAG (II) to yield the tetrahedral intermediate.
Covalent Reaction of PEP with MurA

FIGURE 7. Proposed reaction cycle of E. cloacae MurA involving the Cys-115-PEP adduct. The reaction cycle is derived from the different reaction states of MurA obtained by crystallography with wild-type or mutant enzyme liganded with UNAM, UNAG or UNAGal. The structure identifiers are the same as in Table 1. The cellular UNAG/UNAM ratio controls formation of the dormant complex I. Rapidly reversible exchange with UNAG yields complex II followed by transfer of PEP to UNAG to yield the tetrahedral intermediate, THI (III), which breaks down to the ternary products complex (IV). Covalent reaction of PEP with IV displaces P, to yield complex V followed by rapidly reversible exchange of EP-UNAG and UNAG to complete the cycle. The PEP molecule is shown in cyan, the enolpyruvyl moiety is in green, and the muramic acid moiety is in magenta. The loop containing Cys-115 is shown in gray.

(THI) (III) (Fig. 7). The THI breaks down into reaction products EP-UNAG and inorganic phosphate (IV). PEP enters the active site and reacts with Cys-115, which displaces phosphate to yield complex V. Rapidly reversible exchange of EP-UNAG and UNAG (II) completes the cycle. This covalent reaction cycle (II, III, IV, and V) is driven by formation of the Cys-115-PEP adduct. Depletion of UNAG and an increase in UNAM by the MurB reaction favors formation of the dormant complex I, which likely plays a regulatory role in slowing flux through the pathway.

In vitro, the open unliganded enzyme (VII) interacts first with UNAG to form the binary complex (VIII) (Fig. 8). PEP may then react in a rapidly reversible manner to yield the ternary substrate complex IX or covalently with Cys-115 to yield complex II. Both complexes II and IX are catalytically competent and give rise to the THI (III). The product complex IV may release phosphate to yield complex VI followed by exchange with UNAG to revert to complex VIII, completing the non-covalent cycle (VIII, IX, III, IV, and VI). As both cycles are interconnected via complexes III and IV, it is possible that dormant complex I releases bound PEP in a single turnover reaction from II to III and that subsequent reactions proceed through the non-covalent cycle. With decreasing UNAG/UNAM ratios, a rapidly reversible complex with UNAM (X) may form to which PEP binds covalently and yields the dormant complex. The structure of complex X has not yet been determined, but it is likely that this complex forms readily under high UNAM concentrations. Intriguingly, although the formation of complex IX is central to the non-covalent cycle, it remains the only reaction state that was not able to be captured by crystallography despite numerous trials with different mutant enzymes and UNAG analogues. The pres-
Conclusions—Our findings indicate that cellular depletion of UNAG and concomitant accumulation of UNAM leads to formation of a tight MurA-UNAM complex with PEP covalently attached to Cys-115. This dormant complex displays extreme resilience against dilution and most salts and precipitants used in purification and crystallization. In this study only substrate UNAG, isomer UNAGal (at 1 mM), or product inorganic phosphate (at 50 mM) were able to unlock the complex. Using UNAG analogues and mutant enzymes we were able to generate the same covalent adduct with PEP in vitro, and the now available crystal structures support the original hypothesis that the reaction of MurA enzymes with an active site cysteine residue proceeds through a covalent intermediate.

Previous studies on MurA by other laboratories may have unknowingly been performed with the dormant complex, and we demonstrate using data deposited in the PDB by three different laboratories that those crystal structures were indeed misinterpreted. The tightness of this complex may explain the failure of drug discovery efforts toward the identification of novel reversible inhibitors of MurA with potential as antibiotic drugs. The natural product fosfomycin, discovered half a century ago, remains the only antibiotic drug specifically targeting MurA (12). Fosfomycin and other natural products such as cniacin (17) and terreic acid (16) are covalent MurA inhibitors that essentially compete with PEP for reaction with Cys-115. In contrast, reversible MurA inhibitors require the ability to unlock and open the dormant complex in competition with UNAM and UNAG. However, the mechanism by which UNAG or UNAM induces the open-closed transition is obscure, and the only drug-like molecules crystalized with MurA bind to or stabilize the open enzyme state (15, 23). It appears that identification of the molecular framework required to stabilize a closed enzyme-inhibitor complex with covalently bound PEP is an essential step in the future design of novel MurA inhibitors.

The C115D MurA variant found in Mycobacteria and other species catalyzes enolpyruvyl transfer through a general acid-base mechanism with rapidly reversible binding of PEP (Fig. 8) similar to that of 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS) (which has an active site glutamate) (10). As the C115D enzyme lacks the ability to react with PEP covalently, a tight complex with UNAM cannot be formed, and the enzyme is presumably vulnerable to inhibition by a wider range of small molecule inhibitors able to interfere with the open-closed transition. It is conceivable that the highly conserved active site cysteine residue provides an evolutionary advantage over aspartate, as the covalent reaction between Cys-115 and PEP enables tight regulation by UNAM, provides protection from potential inhibitors through tight complex formation, and primes PEP for instantaneous reaction with substrate UNAG.

Acknowledgments—We thank the Moffitt Chemical Biology Core for use of the protein crystallography and ITC instrumentation and Donna J. Ingles from the Schönbrunn laboratory for help with the manuscript preparation.
