Abstract

The cosmic microwave background (CMB) anisotropies in spherical 3-spaces with a non-trivial topology are studied. This paper discusses the special class of the so-called double-action manifolds, which are for the first time analysed with respect to their CMB anisotropies. The CMB anisotropies are computed for all prism double-action manifolds generated by a binary dihedral and a cyclic group with a group order of up to 180 leading to 33 different topologies. Several spaces are found which show a suppression of the CMB anisotropies on large angular distances as it is found on the real CMB sky. It turns out that two of these spaces possess Dirichlet domains which are not very far from highly symmetric polyhedra like Platonic or Archimedean ones.

1. Introduction

The NASA satellite COBE was not only the first mission to discover fluctuations in the cosmic microwave background (CMB) radiation, but it also revealed that these fluctuations are almost uncorrelated at large angular scales [1]. This important observation was later substantiated by the WMAP mission [2], and it is described by the temperature two-point correlation function

\[ C(\vartheta) := \langle \delta T(\hat{n})\delta T(\hat{n}') \rangle \quad \text{with} \quad \hat{n} \cdot \hat{n}' = \cos \vartheta, \]

where \( \delta T(\hat{n}) \) is the temperature fluctuation in the direction of the unit vector \( \hat{n} \). Since the correlations are most strongly suppressed at angles \( \vartheta \gtrsim 60^\circ \), the scalar measure

\[ S := \int_{\cos(180^\circ)}^{\cos(60^\circ)} d\cos \vartheta \ |C(\vartheta)|^2 \]

is introduced in [2]. Small values of the \( S \) statistics signify a low correlation at large angles.

The observed low values of the \( S \) statistics cannot be easily reconciled with the cosmological \( \Lambda \)CDM concordance model. Among the suggested possibilities to explain this
behaviour is that the spatial space might not be infinite as assumed by the concordance model. The space could possess a non-trivial topology which can lead to multiconnected spaces with a finite volume. Due to the lower cutoff in their wavenumber spectrum \([k]\), these spaces can naturally explain the low correlations in the CMB sky. More details on the cosmic topology can be found in [3–7].

In this paper, it is assumed that the spatial space has a slight positive curvature, so that the simply connected space is the spherical 3-space \(S^3\) which can be embedded in the four-dimensional Euclidean space as a 3-sphere

\[
\vec{x} = (x_0, x_1, x_2, x_3)^T \in S^3
\]

together with the constraint \(|\vec{x}|^2 = x_0^2 + x_1^2 + x_2^2 + x_3^2 = 1\). Using complex coordinates \(z_1 := x_0 + ix_3\) and \(z_2 := x_1 - ix_2\), the coordinate matrix \(u\) can be defined

\[
u := \begin{pmatrix} z_1 \\ iz_2 \\ \bar{z}_1 \\ \bar{z}_2 \end{pmatrix} \in \text{SU}(2, \mathbb{C}) \equiv S^3.
\]

The advantage of the complex representation is that the transformations on \(S^3\) are determined by two \(\text{SU}(2, \mathbb{C})\) matrices denoted as the pair \((g_\ell, g_\nu)\) that acts on the points \(u \in \text{SU}(2, \mathbb{C})\) of the 3-sphere \(S^3 \equiv \text{SU}(2, \mathbb{C})\) by left and right multiplication

\[
g := (g_\ell, g_\nu) : u \rightarrow g_\nu^{-1} u g_\ell.
\]

The points \(u\) and \(g(u)\) are identified if \(g\) belongs to a deck group \(\Gamma\). The 3-sphere \(S^3\) is tessellated in this way by a deck group \(\Gamma\) into as many domains as the deck group has elements that is the order \(|\Gamma|\) of the deck group. The deck groups that lead to spherical multiconnected manifolds are discussed in [8].

In the following, the focus is put on the double-action manifolds that are generated by two finite subgroups \(R\) and \(L\) of Clifford translations. The defining property of Clifford translations is that all points \(u\) are translated by the same spherical distance. Furthermore, they can be divided into left- and right-handed Clifford translations depending on whether the flow lines spiral clockwise and anticlockwise around each other, respectively. In order to obtain a fix-point free group \(\Gamma\), the two subgroups \(R\) and \(L\) have to fulfil some conditions [8]. It turns out that either \(R\) or \(L\) must be cyclic, and we take \(L = Z_n\) as the cyclic subgroup of Clifford translations without loss of generality. The subgroup \(R\) is chosen as the binary dihedral group \(D^*_p\) where the group orders \(n\) and \(p\) must not have a common divisor greater than 1.

The cyclic subgroup \(L = Z_n\) of Clifford translations is generated by

\[
g_{1} = (1, g_\nu) \quad \text{with} \quad g_\nu = \text{diag}(e^{+2\pi i/n}, e^{-2\pi i/n}),
\]

since left-handed Clifford translations are realized by right multiplication. The other elements of \(L\) are obtained from (5) by

\[
g_{ik} = (1, (g_\nu)^k) \quad \text{for} \quad k = 1, \ldots, n.
\]

The binary dihedral group \(R = D^*_p\) has the two generators \(g_{1} = (g_{a1}, 1)\) and \(g_{2} = (g_{a2}, 1)\) with

\[
g_{a1} = \text{diag}(e^{-i\Psi_{\nu c}}, e^{i\Psi_{\nu c}}) \quad \text{and} \quad g_{a2} = \begin{pmatrix} \cos(\Psi_{\nu y}) & -\sin(\Psi_{\nu y}) \\ \sin(\Psi_{\nu y}) & \cos(\Psi_{\nu y}) \end{pmatrix}
\]

where \(\Psi_{\nu c} = 2\pi \left(\frac{2}{p}\right)\) and \(\Psi_{\nu y} = 2\pi \left(\frac{1}{h}\right)\). The deck group \(\Gamma\) consists of all combinations of the elements of the subgroups \(R\) and \(L\). The group order \(|\Gamma|\) of the prism double-action deck group is thus \(|\Gamma| = n p\). In the following, the manifold generated by \(\Gamma\) is denoted as \(DZ(p, n) := S^3/(D^*_p \times Z_n)\) where the letters \(D\) and \(Z\) in \(DZ(p, n)\) indicate the type of the group that is the binary dihedral and the cyclic group with group orders \(p\) and \(n\), respectively.
2. Transforming the CMB observer in double-action manifolds

Before we can proceed to the analysis of the CMB anisotropies of double-action manifolds, we have to consider the transformation of the position $u \in SU(2, \mathbb{C}) \equiv S^3$ of the observer for which the CMB anisotropy is to be computed. Interestingly, it turns out that the statistical CMB properties depend on the observer position within the double-action manifold.

The transformation is realized by applying an arbitrary isometry $t$ to the coordinates

$$u \rightarrow u' = ut, \quad t \in SU(2, \mathbb{C}).$$

Thus, the transformation is defined as right multiplication. Interpreting such a transformation as a shift of the origin of the coordinate system leads to a new representation of the group elements $g_k = (g_{ab}, g_{tk})$ of the deck group as

$$g'_k = (g'_{ab}, g'_{tk}) = (g_{ab}, t^{-1}g_{tk}t), \quad k = 1, 2, \ldots, |\Gamma|,$$

as shown in [9, 10]. Thus, only the elements of the subgroup $L$ are altered. The position dependence can conveniently be described by using the parameterization

$$t(\rho, \alpha, \epsilon) = \begin{pmatrix} \cos(\rho) e^{i\alpha} & \sin(\rho) e^{i\epsilon} \\ -\sin(\rho) e^{-i\alpha} & \cos(\rho) e^{-i\epsilon} \end{pmatrix}$$

for the transformation matrix $t$ with $\rho \in [0, \frac{\pi}{2}], \alpha, \epsilon \in [0, 2\pi]$. In this way the group elements $g_k$ of $\Gamma$ are functions of the parameters $\rho, \alpha,$ and $\epsilon$.

3. Eigenmodes in double-action manifolds

Whether the dependence of the group elements $g \in \Gamma$ on the three parameters $\rho$, $\alpha$, and $\epsilon$ carries over to the correlations in the CMB anisotropy or only a subset of the parameters, is an interesting property of the deck group $\Gamma$ and of the multiconnected manifold. The statistical measures of the CMB are constructed rotationally invariant in order to obtain a measure that does not depend on the orientation of the coordinate system. Thus, if the transformation (9) leads to new group elements that can be considered as a pure rotation of the old ones, the statistical properties of the CMB do not change.

For any two points $P$ and $Q$ in a homogeneous manifold, there exists a global isometry of the manifold taking $P$ to $Q$. This implies that the CMB statistics do not depend on the observer position parameterized by $\rho$, $\alpha$, and $\epsilon$ in this case. For inhomogeneous manifolds there is no such global isometry and the statistical properties of the CMB depend on the observer position, in general. Therefore, the CMB analysis requires a much more detailed investigation. In the case of the inhomogeneous lens spaces $L(p, q)$ which are studied in [11], there is only a $\rho$ dependence, and the position dependent CMB analysis reduces to a one dimensional scan. This applies also to those inhomogeneous lens spaces which are coincidentally double-action manifolds. It turns out, however, that the ensemble averages of the CMB properties of the double-action manifolds $DZ(p, n)$ depend on two parameters, for which $\rho$ and $\alpha$ are chosen.

To show this, we need to discuss the Laplace–Beltrami operator $\Delta$. The eigenmodes of the Laplace–Beltrami operator $\Delta$ on the simply connected spherical manifold $S^3$ can be given as a product of the eigenmodes $|j_a, m_a\rangle$ and $|j_b, m_b\rangle$ of the abstract generators of the Lie algebra $J_a = (J_{a2}, J_{a3}) \in SU_2(2, \mathbb{C})$ and $J_b = (J_{b2}, J_{b3}) \in SU_3(2, \mathbb{C})$, respectively, for more details see [10]. Then, the complete set of eigenmodes for the eigenvalue $E_j := 4(j + 1) = (\beta^2 - 1)$ of the operator $-\Delta$ is obtained by

$$|j; m_a, m_b\rangle := |j, m_a\rangle |j, m_b\rangle \in SO(4, \mathbb{R}).$$
In this notation the action of the generator (5) of the cyclic group \( \mathbb{Z}_n \) is described by \( U_{si} = e^{i(\alpha \pi j / n) \hbar} \). Analogously the action of the two generators (7) of the binary dihedral group \( D_p^* \) are given by \( U_{s1} = e^{i\phi s_e J_{1s}} \) and \( U_{s2} = e^{i\phi s_o J_{2s}} \) with \( \psi_{se} \) and \( \psi_{so} \) defined below equation (7). The eigenmodes on the manifold \( DZ(p, n) \) have to be invariant under the action of \( U_{s1}, U_{s2}, \) and \( U_{s3} \) [12], which is satisfied by

\[
|j, i\rangle = \begin{cases} 
|j; m_a, m_b\rangle & : m_a = 0 \text{ for } j \text{ even} \\
\frac{1}{\sqrt{2}} (|j; m_a, m_b\rangle + (-1)^{j+m_a} |j; -m_a, m_b\rangle) & : m_a > 0
\end{cases}
\]

(12)

where \( j \in \mathbb{N}_0 \setminus \{1, 3, \ldots, 2[\frac{p}{2}] - 1\}, m_b \in \mathbb{Z}, m_a \in \mathbb{N}_0, m_a \equiv 0 \mod p/4, 2m_b \equiv 0 \mod n \) and \( m_a, |m_b| \leq j \). The index \( i \) with \( 1 \leq i \leq \rho^{DZ(p, n)}(\beta) \) counts the degenerated states which belong to the same eigenvalue \( E_j \). The indices \( m_a \) and \( m_b \) can be considered as functions of the degeneracy index \( i \), i.e. \( m_a = m_a(i) \) and \( m_b = m_b(i) \). An analytic expression for the multiplicity \( \rho^{DZ(p, n)}(\beta) \) is stated in table 1. This table also gives the multiplicity of the eigenvalue \( E_j \) for the double-action manifolds \( TZ(24, n) = S^3 / (T^* \times \mathbb{Z}_n), OZ(48, n) = S^3 / (O^* \times \mathbb{Z}_n), \) and \( IZ(120, n) = S^3 / (I^* \times \mathbb{Z}_n) \), where \( T^*, O^*, \) and \( I^* \) are the binary tetrahedral, the binary octahedral, and the binary icosahedral group. The difference between these formulae of the double-action manifolds and the expressions for the multiplicity of the corresponding homogeneous manifolds, see e.g. table 1 in [10], results from the additional constraint \( 2m_b \equiv 0 \mod n \) due to the cyclic group \( \mathbb{Z}_n \). Therefore, the formulae for the multiplicity of the homogeneous manifolds are reproduced for \( n = 1 \).

\( DZ(p, n) \) are inhomogeneous manifolds. For this reason the eigenmodes on the manifold \( DZ(p, n) \) depend on the transformation to a new observer as discussed in section 2. The corresponding operator can be given by

\[
D(i) = D(\alpha + \epsilon, 2\rho, \alpha - \epsilon) = e^{i(\alpha+\epsilon) J_c} e^{i2\rho J_c} e^{i(\alpha-\epsilon) J_c},
\]

(13)

where the coordinates (10) are used for the observer. For the following applications it is convenient to transform the eigenmodes \(|j; m_a, m_b\rangle\) into the spherical basis \(|j; l, m\rangle\), where \( l \)
is the eigenvalue of $\tilde{L} := \tilde{J}_α + \tilde{J}_β$. These two sets of eigenmodes are connected by
\begin{equation}
|j; m_a, m_b\rangle = \sum_l \langle jm_a jm_b | l \rangle |j; l, m\rangle,
\end{equation}
where the $\langle jm_a jm_b | l \rangle$ are the Clebsch–Gordan coefficients [13]. In general, $\langle jm_a jm_b | l \rangle \neq 0$ only for $0 \leq l \leq 2j$ and $m_a + m_b = m$. Therefore, the expansion with respect to the spherical basis $|j; l, m\rangle$ of the eigenmodes $|j; \alpha, \beta\rangle$ is used.

The quadratic sum (17) of the expansion coefficients $\xi^{i, \alpha(i),\mu(i)}_{lm}(DZ(p,n); t)$ results in
\begin{equation}
D(t^{-1})|j, l\rangle = \sum_{l=0}^{2j} \sum_{m=-l}^{l} \xi^{i, \alpha(i),\mu(i)}_{lm}(DZ(p,n); t) |j; l, m\rangle,
\end{equation}
\begin{equation}
\xi^{i, \alpha(i),\mu(i)}_{lm}(DZ(p,n); t) = \begin{cases}
\langle j0 jm | l \rangle D_{m,n}(t^{-1}) & : j \text{ even, } m_a = 0 \\
\frac{1}{2}\sum_{l'=m_a}^{l} \langle jm_a jm - m_a | l' \rangle D_{m-l',m_a}^{l'}(t^{-1}) + (-1)^j \sum_{l'=0}^{m_a} \langle jm_a jm + m_a | l' \rangle D_{m-l',m_a}^{l'}(t^{-1}) & : m_a > 0
\end{cases}
\end{equation}
with $m_a \equiv 0 \mod p/4$ and $2m_b \equiv 0 \mod n$.

Here the definition of the Wigner polynomial
\begin{equation}
D_{m_a,m_b}^{l}(t) := \langle j, m_b | D(t) | j, m_a \rangle = e^{i(\alpha + \epsilon)m_a} d_{m_a,m_b}^{l} (2\rho) e^{i(\alpha - \epsilon)m_b}.
\end{equation}
is used.

The calculation of the ensemble average of the temperature two-point correlation function $C(\theta)$ or the multipole spectrum $C_l$ on the manifolds $DZ(p,n)$ demands the computation of the quadratic sum of the expansion coefficients $\xi^{i, \alpha(i),\mu(i)}_{lm}(DZ(p,n); t)$. This quadratic sum can be rewritten as
\begin{equation}
\frac{1}{2l+1} \sum_{m=-l}^{l} \sum_{i=1}^{r^{S}(\theta)} |\xi^{i, \alpha(i),\mu(i)}_{lm}(DZ(p,n); t)|^2
\end{equation}
\begin{equation}
= \frac{1}{2l+1} \sum_{m=-l}^{l} \left\{ \sum_{m_a,m_b} \big| \langle jm_a jm - m_a | l \rangle d_{m_a,m_b}^{l} (-2\rho) \big|^2 \\
+ \sum_{m_a>0,m_b} \big| (-1)^j \sum_{m_a,m_b} \langle jm_a jm + m_a | l \rangle (jm_a jm + m_a | l) \big| \right\} d_{m_a,m_b}^{l} (-2\rho) \cos (2m_a(\alpha - \epsilon)) \big|.
\end{equation}
The primes at the sums indicate that the summation is restricted by the conditions $m_a \equiv 0 \mod p/4$ and $2m_b \equiv 0 \mod n$. Therefore, the analysis of the CMB statistics can be confined to observer positions within the $\rho-\alpha$ plane by setting $\epsilon = 0$. Furthermore, taking into account the condition $m_a \equiv 0 \mod p/4$ and the symmetry of the sum (17) with respect to the transformation $\rho \rightarrow \frac{\pi}{2} - \rho$, the domain of observer positions exhausting the complete CMB variability can be reduced to the smaller intervals $\alpha \in [0, \frac{\pi}{2}]$ and $\rho \in [0, \frac{\pi}{2}]$.

4. CMB anisotropy on large angular scales

The quadratic sum (17) of the expansion coefficients $\xi^{i, \alpha(i),\mu(i)}_{lm}$ allows the computation of the ensemble average of the multipole moments $C_l$ for the space $M = DZ(p,n)$.
$$C_l = \frac{1}{2l+1} \sum_{m=-l}^{l} |a_{lm}|^2$$

$$= \sum_{\beta} T^2_\beta(\beta) \frac{P(\beta)}{2l+1} \sum_{m=-l}^{l} \sum_{i=1}^{r_{\beta}} s^p_{\beta,im}(\mathcal{M}; t)^2. \quad (18)$$

The initial power spectrum is $P(\beta) \sim 1/(E_\beta^{-2} - \eta)$ and $T^2_\beta(\beta)$ is the transfer function for which the same cosmological model as in [10] is used. After the multipole moments $C_l$ have been obtained, the ensemble average of the two-point correlation function $C(\theta)$ can be computed using

$$C(\theta) = \sum_{l} \frac{2l+1}{4\pi} C_l P_l(\cos \theta). \quad (19)$$

This in turn leads to the $S$ statistics using equation (2), and the extent of the suppression of the CMB correlations on large angular scales can be calculated. In the following, we always normalize the $S$ statistics to that of the homogeneous $S^3$ space. Thus, values of the $S$ statistics below 1 indicate models that possess a stronger CMB suppression than the model based on the simply connected spherical $S^3$ space.

We compute the $S$ statistics along these lines for sets of cosmological parameters which are close to the standard concordance model of cosmology [14]. The parameters are obtained from the LAMBDA website (lambda.gsfc.nasa.gov), see the WMAP cosmological parameters of the model 'olcdm+sz+lens' using the data 'wmap7+bao+snconst', which are $\Omega_b = 0.0485$, $\Omega_{cdm} = 0.238$, the Hubble constant $h = 0.681$, and the spectral index $n_s = 0.961$. The density parameter of the cosmological constant $\Omega_\Lambda$ is varied such that the total density parameter $\Omega_{\text{tot}}$ is in the interval $\Omega_{\text{tot}} = 1.001, \ldots, 1.05$. Thus, we consider spherical models that are almost flat. The cosmological parameters stated above lead to the constraint $0.99 < \Omega_{\text{tot}} < 1.02$ (95% CL), so that our chosen $\Omega_{\text{tot}}$ interval covers slightly more than 99% CL. For each value of $\Omega_{\text{tot}}$ the correlation measure $S$ is calculated for numerous observer positions described by the parameters $\alpha$ and $\rho$. The values of $\alpha$ and $\rho$ are obtained from a sufficiently dense rectangular mesh with $\alpha \in [0, \frac{\pi}{p}]$ and $\rho \in [0, \frac{\pi}{4}]$. This leads to almost 4.3 million simulations up to $\Omega_{\text{tot}} = 1.05$.

The minima of the $S$ statistics

$$S_{\min(\alpha, \rho)} = \min_{\alpha, \rho}(\frac{S(\alpha, \rho)}{S_{S^3}}) \quad (20)$$

are determined for fixed values of $\Omega_{\text{tot}}$ for all 33 topologies $DZ(p, n)$ with a group order up to 180 and are plotted in figure 1. There are several spaces that have a CMB suppression more than two times stronger than in the $S^3$ space. The $DZ(16, 3)$ space has a minimum at $\Omega_{\text{tot}} = 1.036$ with $S_{\min(\alpha, \rho)} = 0.291$. Thus it has three times smaller correlations compared to the $S^3$ space. Notice that this model has at the upper boundary of the 95% CL interval, i.e. at $\Omega_{\text{tot}} = 1.02$, a noteworthy suppression factor of about 0.5. Another candidate is provided by the double-action space $DZ(20, 3)$ which has two almost equal minima at $\Omega_{\text{tot}} = 1.020$ and at $\Omega_{\text{tot}} = 1.044$. The minima are $S_{\min(\alpha, \rho)} = 0.419$ and $S_{\min(\alpha, \rho)} = 0.416$, respectively. Therefore, if one allows for $\Omega_{\text{tot}}$ only values as large as $\Omega_{\text{tot}} = 1.02$, the best candidate would be provided by the $DZ(20, 3)$ space. If one restricts $\Omega_{\text{tot}}$ to even smaller values, that is, to even flatter models, then several other $DZ(p, n)$ spaces possess the lowest CMB correlations. With $\Omega_{\text{tot}} < 1.015$ one finds the four models $DZ(24, 5)$, $DZ(24, 7)$, $DZ(28, 5)$, and $DZ(32, 5)$, satisfying $S_{\min(\alpha, \rho)} < 0.5$. The corresponding values of $S_{\min(\alpha, \rho)}$ are given in table 2, where the parameters of the best models are listed for all 33 manifolds restricted to $\Omega_{\text{tot}} \leq 1.05$. 

6
Figure 1. The minima of the $S$ statistics, equation (2), taken over all positions in the $\alpha - \rho$ plane, are plotted as a function of $\Omega_{\text{tot}}$ for all $DZ(p, n)$ spaces with $|\Gamma| = pn \leq 180$. The correlation measure $S$ is normalized to that of the $S^3$ space.

The only manifold where the first minimum of $S_{\text{min}(\alpha, \rho)}$ lies outside this $\Omega_{\text{tot}}$ interval is $DZ(8, 3)$ such that its value in table 2 is determined by this $\Omega_{\text{tot}}$ cut-off. The minimum with $S_{\text{min}(\alpha, \rho)} = 0.060$ occurs at $\Omega_{\text{tot}} = 1.15$ with $\alpha = \rho = 0$. Although $DZ(8, 3)$ has a very strong suppression, this value of $\Omega_{\text{tot}}$ is too large in order to be compatible with the current cosmological observations.

Let us discuss the favourite $DZ(16, 3)$ in more detail. Since figure 1 only shows the minimum $S_{\text{min}(\alpha, \rho)}$, the degree of variation with respect to the observer position parameterized by $\alpha$ and $\rho$ is eliminated. This information is provided in figure 2(a) where the variation due to the position is shown as a grey band for the $DZ(16, 3)$ space. In addition, the panel shows the normalized correlation measure $S$ of the homogeneous $D_{16}$ and $L(3, 1)$ spaces (dashed and dotted curves) which are generated by the groups $D_{16}^*$ and $Z_3$. Since $DZ(16, 3) = S^3 / (D_{16}^* \times Z_3)$, these are the subgroups $R$ and $L$ generating $DZ(16, 3)$. The figure 2(a) reveals that it is the behaviour of the homogeneous $D_{16}$ space which is responsible for the main behaviour of the inhomogeneous $DZ(16, 3)$. Because of this relevance for the $DZ(p, n)$ spaces, the table 3 lists the minima of their $S$ statistics together with the value of $\Omega_{\text{tot}}$ where the minima occur. As in previous cases the $\Omega_{\text{tot}}$ interval is restricted to $\Omega_{\text{tot}} = 1.001, \ldots, 1.05$. The table reveals that all prism spaces $D_p$, $p \leq 72$, possess only a moderate suppression of large-angle correlations below $\Omega_{\text{tot}} = 1.05$. The minimum for $D_{16}$ at $\Omega_{\text{tot}} = 1.028$ can also be seen in figure 2 (dashed curves).

There are five manifolds $DZ(16, n)$ up to group order 180 which have the group $D_{16}^*$ as a subgroup. As a further example the variation due to the observer position in $DZ(16, 9)$ is shown in figure 2(b) where the variation is larger than for the manifold $DZ(16, 3)$. The increased variability can be understood in terms of the number of inhomogeneous translations within the deck group. An inhomogeneous group element transforms different points $\vec{x} \in S^3$ to varying spherical distances. This contrasts to Clifford transformations where all points $\vec{x} \in S^3$ are shifted by the same spherical distance. The deck group of the manifold $DZ(16, 3)$ contains 30 inhomogeneous transformations and 18 Clifford transformations. The number of inhomogeneous translations increases to 120 for the manifold $DZ(16, 9)$. The large variability of the $S$ statistics can be explained by this large number, since the CMB dependence on the
Table 2. For the 33 prism double-action manifolds $DZ(p, n) = S^3/(D_p \times \mathbb{Z}_n)$ up to the group order $|\Gamma| = 180$, the models with the lowest CMB correlations on large angular scales are given. The parameters $\Omega_{\text{tot}}, \rho$, and $\alpha$ specify the model which leads to a minimal value in the $S$ statistics.

| Manifold $\mathcal{M}$ | $S_{\text{min}}(\Omega_{\text{tot}}, \alpha, \rho)$ | $\Omega_{\text{tot}}$ | $\rho$ | $\alpha$ |

observer position is the more pronounced, the more inhomogeneous translations are in the deck group. Conversely, the variation width must shrink to zero if all group elements are Clifford transformations whose transformation properties are independent of $x \in S^3$. To emphasize this point figure 3 displays the observer position dependence for the manifolds $DZ(16, 3)$ and $DZ(16, 9)$ of the normalized $S$ statistics computed at the same value of $\Omega_{\text{tot}} = 1.036$. It is clearly seen that the $DZ(16, 9)$ space has a severe position dependence compared to the space $DZ(16, 3)$. Furthermore, both models posses only a modest variation with respect the parameter $\alpha$. Thus, the main variation is due to an observer shift in the $\rho$ direction.

5. The shape of the Dirichlet domains

As described in section 2 the representation of the group elements of the deck group $\Gamma$ changes according to equation (9). As a consequence the Dirichlet domain alters due to shifts of the
observer position. The Dirichlet domain $\mathcal{F}$ is defined as the set of points $u \in S^3$ that cannot be transformed any closer to the observer $u_o$ by applying the elements of the deck group $\Gamma$, i.e.

$$u \in \mathcal{F} \text{ if } d(u_o, u) \leq d(u_o, g(u)) \text{ for all } g \in \Gamma,$$

(21)

where $d(u_1, u_2)$ measures the spherical distances between the points $u_1, u_2 \in S^3$. It is instructive to compare the shape of the Dirichlet domains at the positions of the observer where the values for the $S$ statistics are extremal. The figure 4 shows the Dirichlet domains of the spherical regular polyhedral spaces generated by the binary tetrahedral group $T^*$, the binary octahedral group $O^*$, and the binary icosahedral group $I^*$ which are introduced in
Figure 3. The normalized correlation measure $S$ is shown in dependence on the observer position which is parameterized by $\rho$ and $\alpha$. The lower surface belongs to the double-action space $DZ(16, 3)$ at $\Omega_{\text{tot}} = 1.036$. It has only a mild position dependence compared to the manifold $DZ(16, 9)$ (upper surface) computed for the same $\Omega_{\text{tot}}$. The figure reveals that the position dependence is more pronounced with respect to the parameter $\rho$ than to $\alpha$ in both cases.

Table 3. The lowest CMB correlations on large angular scales $S_{\text{min}}(\Omega_{\text{tot}})$ are given with the corresponding $\Omega_{\text{tot}}$ for all prism spaces $D_p$ generated by the binary dihedral groups $D_{p\star}$ up to the group order $|\Gamma| = p = 72$. The minima are determined for the interval $\Omega_{\text{tot}} = 1.001, \ldots, 1.05$. The prism spaces are homogeneous, and thus an observer position is not required in this table.

| Manifold $M$ | $S_{\text{min}}(\Omega_{\text{tot}})$ | $\Omega_{\text{tot}}$ |
|-------------|-------------------------------|-----------------|
| $D_8$       | 0.988                         | 1.050           |
| $D_{12}$    | 0.684                         | 1.050           |
| $D_{16}$    | 0.780                         | 1.028           |

| $D_{48}$    | 0.854                         | 1.003           |
| $D_{52}$    | 0.854                         | 1.002           |
| $D_{56}$    | 0.855                         | 1.002           |
| $D_{60}$    | 0.857                         | 1.002           |
| $D_{64}$    | 0.858                         | 1.002           |
| $D_{68}$    | 0.859                         | 1.001           |
| $D_{72}$    | 0.860                         | 1.001           |

These groups consist only of Clifford transformations, so that the Dirichlet domains are independent of the observer position, i.e. these manifolds are homogeneous.

Let us now turn to the $DZ(8, 3)$ space which has its first minimum in the $S$ statistics at $\Omega_{\text{tot}} = 1.15$. Figure 1 shows its behaviour up to $\Omega_{\text{tot}} = 1.05$ and the decline towards higher $\Omega_{\text{tot}}$ is already visible. In the range $\Omega_{\text{tot}} = 1.025, \ldots, 1.065$ the minimum in the $S$ statistics
Figure 4. The Dirichlet domains generated by the binary tetrahedral group $T^*$ (blue), the binary octahedral group $O^*$ (yellow), and the binary icosahedral group $I^*$ (red) are shown. These three regular polyhedral spaces are homogeneous manifolds.

Figure 5. The Dirichlet domains for $DZ(8, 3)$ are shown with $\rho = 0.479$ and $\alpha = \frac{\pi}{4}$ in panel (a) and with $\rho = 0$ and $\alpha = 0$ in panel (b).

is achieved at $\rho = 0.479$ and $\alpha = \frac{\pi}{4}$ whereas the maximum occurs at $\rho = 0$ and $\alpha = 0$. The Dirichlet domains for these positions are shown in figure 5. Interestingly, the orientations are reversed at the actual minimum at $\Omega_{\text{tot}} = 1.15$, i.e. the minimum occurs at $\rho = 0$ and $\alpha = 0$ and the maximum at $\rho = 0.479$ and $\alpha = \frac{\pi}{4}$. A further interesting point is that the Dirichlet domain of $DZ(8, 3)$ is at $\rho = \frac{1}{2} \arccos(1/\sqrt{3}) \simeq 0.479$ and $\alpha = \frac{\pi}{4}$ identical to that of the binary tetrahedral space $T$ shown in figure 4. It is remarkable that in the range $\Omega_{\text{tot}} = 1.025, \ldots, 1.065$ the favoured geometric shape is the same for both the $DZ(8, 3)$ space and the binary tetrahedral space $T$, since the wave number spectrum starts at $\beta = 5$ for the former and at $\beta = 7$ for the latter (see table 1). Furthermore, their multiplicities are also different. This fact is remarkable in view of the so-called well-proportioned conjecture [15] which states that the CMB suppression on large angular scales is the more pronounced, the more well-proportioned the Dirichlet domain is. Thus, one would expect the position at $\rho = 0.479$ and $\alpha = \frac{\pi}{4}$ always to be the one with the minimum in the $S$ statistics, but this is not the case. This provides therefore a counterexample to the conjecture. We would like to clarify
that although the Dirichlet domains of the binary tetrahedral space $T$ and of the $DZ(8,3)$ space at $\rho = \frac{1}{2} \arccos(1/\sqrt{3})$ and $\alpha = \frac{\pi}{2}$ are identical, they nevertheless belong to different spaces since the gluing rules, which describe how to connect the faces, are different.

The discussion in section 4 shows that a very interesting double-action space is provided by $DZ(16,3)$ having a strong CMB anisotropy suppression at $\Omega_{\text{tot}} = 1.036$. The Dirichlet domain for the observer who sees the minimal CMB anisotropy, i.e. $\rho = 0.385$ and $\alpha = 0$, is depicted in figure 6(a). A comparison with figure 4 reveals the similarity with the homogeneous space generated by the binary octahedral group $O$. However, the Dirichlet domain possesses not the symmetry of the fundamental cell of the group $O$, since the Dirichlet domain that exactly matches that of the binary octahedral group $O$ occurs in $DZ(16,3)$ at $\rho = \frac{1}{2} \arccos(1/\sqrt{3}) \simeq 0.479$ and $\alpha = 0$. At this position the value for the $S$ statistics is $S = 0.346$ which is larger than the minimal value $S = 0.291$ as revealed by table 2. Therefore, although both Dirichlet domains are similar, the deviation demonstrates that the best Dirichlet domain with respect to maximal CMB suppression is not the one with the most well-proportioned fundamental cell. This difference is not surprising since the wave number spectrum starts at $\beta = 5$ for $DZ(16,3)$ and at $\beta = 9$ for the binary octahedral space $O$ (see table 1). Figure 6(b) shows the Dirichlet domain of $DZ(16,3)$ at $\rho = \frac{\pi}{2}$ and $\alpha = 0$ which corresponds to the observer seeing the largest CMB anisotropy power on large angular scales at $\Omega_{\text{tot}} = 1.036$.

The above results reflect the complexity of equation (18) which is used to compute the CMB correlations. Equation (18) shows that the local physics described by the transfer function $T_l(\beta)$ is interconnected with the global structure described by the quadratic sum over the coefficients $\xi_{\ell m}(V; t)$. For fixed value of $l$, both contributions depend on the wave number $\beta$ so that neither factor is responsible on its own for a pronounced suppression of correlations. Attempts to explain the low correlations with only the first few modes in $\beta$ turn out to fail since there is no sharp boundary between the modes determining the large scale behaviour and those that do not. So that one cannot simply analyse a truncated series instead of equation (18).

In section 4 it was shown that a much stronger observer-position dependence with respect to the $S$ statistics occurs in $DZ(16,9)$ compared to $DZ(16,3)$. The $DZ(16,9)$ space possesses a first minimum in the $S$ statistics at $\Omega_{\text{tot}} = 1.006$ for the observer at $\rho = 0.086$ and $\alpha = 0$. At this value of $\Omega_{\text{tot}}$ the maximal CMB anisotropy even exceeds that of the simply connected $S^3$. 
space for an observer at $\rho = \frac{\pi}{4}$ and $\alpha = 0$. Figure 7 shows for both positions the corresponding Dirichlet domains emphasizing that the large variability in the $S$ statistics is also reflected in the Dirichlet domains. The $DZ(16, 9)$ space cannot have a Dirichlet domain corresponding to regular polyhedral spaces as shown in figure 4 since the group orders do not match.

Although deviations from the predictions of the well-proportioned conjecture are found, it is nevertheless remarkable that the Dirichlet domains of two regular polyhedral spaces play a role with respect to the CMB anisotropy suppressions in double-action manifolds $DZ(p, n) = S^3 / (D^*_p \times Z_n)$.

6. Comparison of prism double-action manifolds with observations

Up to now the power of the correlation function for the manifolds $DZ(p, n)$ on scales larger than $60^\circ$ is studied without reference to observations. In this section the correlations of the CMB for these models are compared with that of the WMAP 7 yr data on all angular scales $\vartheta \in [0^\circ, 180^\circ]$ using the correlation function of the ILC 7 yr map [16]. The integrated weighted temperature correlation difference

$$I := \int_{-1}^{1} d \cos \vartheta \frac{(C_{\text{model}}(\vartheta) - C_{\text{obs}}(\vartheta))^2}{\text{Var}(C_{\text{model}}(\vartheta))} \quad (22)$$

is suited for such a comparison of the observed correlation function $C_{\text{obs}}(\vartheta)$ with that of the model $C_{\text{model}}(\vartheta)$, where the ensemble average due to the Gaussian initial condition is used for the latter. Furthermore, the model is normalized to the angular power spectrum of the WMAP data using the multipoles between $l = 20$ and 45. The cosmic variance of the model is computed using

$$\text{Var}(C(\vartheta)) \approx \sum_l \frac{2l + 1}{8\pi^2} \left| C_l(\cos \vartheta) \right|^2. \quad (23)$$

The correlation difference $I$ is calculated for three different correlation functions $C_{\text{obs}}(\vartheta)$ which are computed in all three cases from the ILC 7 yr map of the WMAP data but are based on different subsets of pixels. One correlation function $C_{\text{obs}}(\vartheta)$ is obtained from the complete ILC 7 yr map but the other two apply the KQ75 7 yr and KQ85 7 yr masks. The two masks are provided by [16], where the KQ85 7 yr and the KQ75 7 yr masks include 78.3% and 70.3% of the sky, respectively. For a discussion to this topic see e.g. [10].
The values of the $I$ statistics are computed for all 33 prism double-action manifolds $DZ(p, n)$ up to the group order $|\Gamma| = 180$ for the same values of $\Omega_{\text{tot}}$, $\alpha$, and $\rho$ as in the previous sections. For a given manifold the best value for the $I$ statistics, i.e.

$$I_{\text{min}}(\alpha, \rho, \Omega_{\text{tot}}) = \min_{\alpha, \rho, \Omega_{\text{tot}}} I(\alpha, \rho, \Omega_{\text{tot}}),$$

is then determined where the $\Omega_{\text{tot}}$ interval is restricted to $\Omega_{\text{tot}} \in [1.001, 1.05]$. These values are plotted as full disks in figure 8 where the three panels refer to the three different observational correlation functions $C^{\text{obs}}(\vartheta)$. A survey of lens spaces $L(p, q)$ is provided in [11] where the $S$ statistics as well as the $I$ statistics are analysed for all lens spaces $L(p, q)$ up to the group order $p = 72$. It is found that two sequences of lens spaces exist with a relatively strong CMB anisotropy suppression. These data are also shown in figure 8 where the correlation difference $I$ of these lens spaces is plotted as open circles for the homogeneous spaces $L(p, 1)$ and as open squares for the inhomogeneous spaces $L(p, q)$, $q > 1$. Three $DZ(p, n)$ spaces immediately attract attention because their values of the $I$ statistics are significantly smaller than in any of the lens spaces $L(p, q)$. These three spaces are $DZ(16, 3)$, $DZ(8, 3)$, and $DZ(20, 3)$. The double-action manifold $DZ(16, 3)$ leads to the best match for all three observational correlation functions $C^{\text{obs}}(\vartheta)$, that is with the KQ75 7 yr or KQ85 7 yr mask or without a mask at all. The two other spaces change the second and third position with respect to the lowest value of $I_{\text{min}}(\alpha, \rho, \Omega_{\text{tot}})$ depending on the selected pixels of the ILC map. Using the KQ75 7 yr or KQ85 7 yr mask the space $DZ(20, 3)$ provides a slightly better description of the CMB data than $DZ(8, 3)$. This relation reverses if no mask is applied.

This comparison reveals that the three double-action manifolds $DZ(16, 3)$, $DZ(8, 3)$, and $DZ(20, 3)$ produce the lowest CMB correlations among the two classes of inhomogeneous spaces $DZ(p, n)$ and $L(p, q)$.

7. Summary and discussion

This paper studies whether a special class of spherical topologies can alleviate the apparent disagreement between the standard concordance model of cosmology and measurements of the low power at large scales in the cosmic microwave background (CMB) maps. The cosmological observations point to an almost spatially flat cosmos. Thus, we restrict the analysis to spherical models that are almost flat by confining the total density parameter $\Omega_{\text{tot}}$ to the interval $\Omega_{\text{tot}} = 1.001, \ldots, 1.05$. The space of such cosmological models is the simply connected 3-sphere $S^3$ if the model should be close to the concordance model. These concordance-like models produce, however, more correlations in the CMB temperature fluctuations on large angular scales as observed in CMB sky. This disagreement can be alleviated by considering instead of the simply connected 3-sphere $S^3$ a multiconnected space $M = S^3/\Gamma$ which is obtained from the 3-sphere $S^3$ by tessellating it under the action of a deck group $\Gamma$.

Multiconnected spherical spaces can be classified into several groups, see e.g. [8]. On the one hand there are three deck groups which lead to regular polyhedral spaces. These are obtained by applying the binary tetrahedral group $T^*$, the binary octahedral group $O^*$, or the binary icosahedral group $I^*$ to the 3-sphere $S^3$. The polyhedral spaces are homogeneous in the sense that their fundamental domains defined as a Dirichlet domain look the same independent of the position of the CMB observer. The important implication thereof is that the statistical CMB properties do not depend on the CMB observer. Inhomogeneous manifolds possess such a position dependence, in general. It turns out that the regular polyhedral spaces yield CMB anisotropies with a normalized $S$ statistics, equation (2), of $S/S_{S^3} \simeq 0.11$. This is the strongest suppression of CMB correlations on large angles found so far.
Figure 8. The minima of the $I$ statistics taken over $\alpha$, $\rho$, and $\Omega_{\text{tot}}$ are plotted for the double-action manifolds $DZ(p, n)$ as full disks. The open circles and open boxes represent the homogeneous and inhomogeneous lens spaces $L(p, q)$. These are complete for $p \leq 72$ and, in addition, the group order $p = 120$ is also shown. The $\Omega_{\text{tot}}$ interval is restricted for both space classes to $\Omega_{\text{tot}} \in [1.001, 1.05]$. 

Class. Quantum Grav. 29 (2012) 215005

R Aurich and S Lustig
In addition to these three manifolds there are the so-called prism spaces, which are generated by the binary dihedral group \( Dp^* \). The prism spaces are homogeneous and are analysed up to the group order \( p = 72 \) in [10], see also [12]. The CMB suppression of some prism spaces can be as low as \( S/S_{S^3} \simeq 0.8 \ldots 0.9 \) for \( \Omega_{\text{tot}} = 1.001, \ldots, 1.05 \) as shown in table 3. The prism space \( D_{12} \) drops even to \( S/S_{S^3} \simeq 0.68 \) at \( \Omega_{\text{tot}} = 1.05 \) being the boundary of the imposed \( \Omega_{\text{tot}} \) interval. This shows that the regular polyhedral spaces suppress the CMB anisotropies on large angles stronger than the prism spaces.

A further class of spherical spaces are the lens spaces \( L(p, q) \) which are homogeneous for \( q = 1 \) and inhomogeneous for \( q > 1 \). The CMB properties of the lens spaces are analysed systematically in the survey presented in [11], and some interesting sequences of lens spaces \( L(p, q) \) are found. But their CMB suppression is less pronounced compared to the regular polyhedral spaces. Typical values are in the range \( S/S_{S^3} \simeq 0.5 \ldots 0.6 \) [11].

Therefore, the question emerges whether other classes of multiconnected spherical spaces can do it better. The next class is given by the so-called double-action manifolds where the group elements are composed of a right- and a left-handed Clifford transformation belonging to homogeneous deck groups \( R \) and \( L \). Choosing \( L = Z_n \) as the cyclic subgroup of Clifford translations and the subgroup \( R \) as the binary dihedral group \( Dp^* \), leads to the prism double-action manifolds \( DZ(p, n) = S^3/\langle Dp^* \times Z_n \rangle \) to which this paper is devoted. Three further classes of double-action manifolds can be generated by the binary polyhedral groups leading to \( TZ(24, n) := S^3/\langle T^* \times Z_n \rangle \), \( OZ(48, n) := S^3/\langle O^* \times Z_n \rangle \), and \( IZ(120, n) := S^3/\langle I^* \times Z_n \rangle \). These three groups do not possess analytical expressions for their eigenmodes in terms of Wigner polynomials and require a separate numerical treatment. Their analysis is reserved to another paper.

The CMB suppression of the double-action manifolds \( DZ(p, n) \) is compared with that of the lens spaces \( L(p, q) \) in figure 8. Three spaces attract attention because they reveal a stronger CMB suppression than all studied lens and prism spaces. These are the prism double-action manifolds \( DZ(16, 3) \), \( DZ(8, 3) \), and \( DZ(20, 3) \). The smallest large-angle correlations are seen in \( DZ(16, 3) \) at \( \Omega_{\text{tot}} = 1.036 \), where \( S/S_{S^3} \simeq 0.291 \) is reached. If one insists on the density interval \( 0.99 < \Omega_{\text{tot}} < 1.02 \) (95% CL), the space \( DZ(20, 3) \) provides the most interesting prism double-action manifold since it has at \( \Omega_{\text{tot}} = 1.02 \) a suppression of \( S/S_{S^3} \simeq 0.419 \). Although this suppression is remarkable, it is nevertheless less pronounced than that found in the regular polyhedral spaces.

Besides the three classes \( TZ(24, n) \), \( OZ(48, n) \), and \( IZ(120, n) \), which are not studied in this paper, there are linked action manifolds [8] that are not analysed with respect to their CMB suppression until now. Except for these cases, one can summarize that the regular polyhedral spaces are the most promising spherical spaces with respect to their CMB suppression followed by some members of the class of double-action manifolds \( DZ(p, n) \), notably the spaces \( DZ(16, 3) \), \( DZ(8, 3) \), and \( DZ(20, 3) \).

Acknowledgments

We would like to thank the Deutsche Forschungsgemeinschaft for financial support (AU 169/1-1). The WMAP data from the LAMBDA website (lambda.gsfc.nasa.gov) were used in this work.
