Primary leptomeningeal melanoma in an adolescent: Case report and review of the literature

Warren Chang, MD; Andrew Scarano, MD; and Laurence Berg, MD

A previously healthy 16-year-old male patient came to the emergency department with a six-week history of left posterior hip pain following a head-on ATV collision. After failing conservative therapy, he was found to have weakness and atrophy of the left lower extremity on exam. MRI demonstrated an epidural mass that was hyperintense on T1 and hypointense on T2. Biopsy of the mass revealed a melanocytic lesion; further lesions were identified in the lungs, which biopsy proved to be malignant melanoma. Dermoscopy of the entire body, anoscopy, and retinal exam were negative for melanoma; a whole-body PET scan did not reveal any further lesions or evidence of a primary lesion. Given the lack of a primary lesion, this was thought to be a primary leptomeningeal melanoma. Primary melanomatous tumors of the spine are rare entities, with fewer than 40 cases described in the literature. This case was unique due to the patient's very young age and the presence of metastases on presentation.

Case report

A 16-year-old male Caucasian patient with no significant past medical history presented to the emergency department with a six-week history of posterior, sharp left hip pain. He had recently been involved in a head-on ATV-versus-trail-bike collision. At the time of the incident, he was not wearing a helmet, remained mounted on the ATV, and was able to ambulate without obvious difficulty immediately after. He was prescribed oral NSAIDs, with only minimal relief of symptoms over the course of the next two weeks.

On followup, his PCP suspected sciatica and subsequently prescribed oral corticosteroids. Five days later, the
patient returned to the emergency department with severe worsening of the hip pain. During that visit, plain films of the lumbar spine and left hip were obtained but were unremarkable. The patient was seen in PM&R for further evaluation. Atrophy of the left gastrocnemius and soleus muscles was identified on physical exam. Additional imaging (obtained with noncontract MRI of the lumbar spine) showed a 4.5x1.8cm tubular structure in the spinal canal that was hyperintense on T1-weighted images (Fig. 1) and hypointense on T2-weighted images (Fig. 2). The lesion had significant mass effect on the left sacral nerve roots, with hemorrhage extending into the S1-S2 and S2-S3 neuroforamina and accompanying severe central spinal stenosis. Given the history of recent trauma and patient age, the mass was suspected to most likely represent an epidural hematoma.

The patient was brought to the OR for emergent evacuation of the suspected hematoma and complete L1 hemilaminectomy. A grossly bluish, sticky, and well-organized clotted mass was identified, removed, and sent to pathology. The specimen was read as consistent with a melanocytic neoplasm; due to the low proliferation rate, the tumor was thought to be more likely a benign melanocytoma. However, given the possibility of metastasis, CT images of chest/abdomen/pelvis and MRI of the brain and total spine were obtained. MRI of the brain and total spine found no significant abnormalities. CT revealed multiple small pulmonary nodules. In order to rule out metastatic disease, two pulmonary nodule biopsies were obtained and interpreted as malignant melanoma; the lesions appeared black when removed (Figs. 3-4). A thorough full-body dermoscopy, retinal exam, and anoscopy did not identify any melanocytic lesions or suspicious moles. Therefore, the primary lesion was thought to be of spinal origin, most likely lumbosacral leptomeningeal or an epidural melanocyte stem-cell cluster. After the initial lesion was resected, molecular testing showed that the patient’s melanoma was c-kit positive; the patient was subsequently treated with imatinib, and he clinically improved over the next several months. At the time of this report, the patient was in remission from his melanoma.
Discussion

MRI findings of spinal-cord lesions can help suggest the presence of melanomas, melanocytomas, and other pigmented lesions (6, 10). However, differentiating between pigmented tumors and other entities can be confusing. Tumors with high T1 signal and low to isointense T2 signal and iso- to hyperintensity on CT should be suspected as melanomas. This imaging pattern occurs in malignant melanomas due to the paramagnetic effect of stable free radicals and the metal-scavenging effects of melanin (11). However, this pattern can be seen in other lesions as well, and melanomas in general can be quite heterogeneous.

Differential diagnosis would also include subacute epidural hematoma. This was initially suspected in this case due to the history of trauma; it presents with high signal intensity on T1 due to the presence of intracellular and extracellular methemoglobin, which has a short T1 due to dipole-dipole interactions (11). Hyperintensity on T1-weighted imaging is seen in fat or hemorrhage as well as in melanoma, whereas hypointensity on T2-weighted imaging could conceivably be seen in subacute hemorrhage. This case demonstrates that melanoma should always be on the differential diagnosis of a mass lesion showing characteristic imaging findings, regardless of the patient’s age, other demographics, or risk factors.
